

70. 2.  
HARVARD UNIVERSITY.

LIBRARY OF THE MASS. MED. COLLEGE.

*Rules and Regulations.*

1. Students attending any of the Lectures in the Massachusetts Medical College may take books from the Library during the course, by depositing Five Dollars with the Dean ; and the students of any of the Medical Professors may have the same privilege on the same terms throughout the year.

2. The Library shall be open on the afternoon of every Saturday, from 3 to 5 o'clock, for the delivery and return of books.

the sum deposited ; otherwise the whole amount will be returned to the depositor, when he ceases to use the Library.

THE  
PRINCIPLES AND PRACTICE  
OF  
MEDICINE.

BY

JOHN ELLIOTSON, M.D., CANTAB.; F.R.S.

President of the Royal Medical and Chirurgical Society;  
President of the Phrenological Society;  
Late Professor of the Principles and Practice of Medicine, and of Clinical Medicine,  
and Dean of the Faculty of Medicine, in University-College, London;  
Late Senior Physician to the University-College-Hospital;  
Fellow of the Royal College of Physicians;  
Formerly Physician to Saint Thomas's Hospital,  
And President of the Royal Medical Society of Edinburgh.

EDITED BY

NATHANIEL ROGERS, M.D.

Member, and late President, of the Hunterian Society of Edinburgh; and Corresponding Member  
of the Medico-Chirurgical Society of Dublin;

AND

ALEXANDER COOPER LEE.

FIRST AMERICAN, FROM THE SECOND LONDON EDITION,  
GREATLY ENLARGED AND IMPROVED.

WITH NOTES AND ADDITIONS BY

THOMAS STEWARDSON, M.D.

PHYSICIAN TO THE PENNSYLVANIA HOSPITAL.

PHILADELPHIA:  
CAREY AND HART.  
1844.

WB  
E46p  
1844

---

Entered according to act of Congress, in the year 1843, by

CAREY AND HART,

In the office of the Clerk of the District Court for the Eastern District of Pennsylvania.

---

---

T. K. & P. G. COLLINS, Printers.

TO  
HENRY, LORD BROUGHAM,

BARON BROUGHAM AND VAUX, F.R.S.,

MEMBER OF THE NATIONAL INSTITUTE OF FRANCE;

THE ABLE, LIBERAL, AND ENLIGHTENED PROMOTER OF KNOWLEDGE  
IN ALL ITS DEPARTMENTS;

TO WHOM

THE LITERATURE OF THE COUNTRY IS INDEBTED FOR SOME  
OF ITS BRIGHTEST ORNAMENTS;

AND

THE COUNTRY ITSELF FOR SOME OF ITS BEST LAWS;

WHOSE EXERTIONS

THROUGH THE PRESS, AT THE BAR, AND IN THE SENATE,

HAVE RAISED FOR HIM

“A MONUMENT MORE DURABLE THAN BRASS;”

WITH

PROFOUND ADMIRATION OF HIS TRANSCENDENT TALENTS, BUT STILL GREATER  
RESPECT FOR THEIR APPLICATION,

THIS VOLUME IS INSCRIBED.

## PREFACE TO THE SECOND EDITION.

---

WHEN this Work first appeared, it had to compete with several long established favourites, and to encounter some deeply-rooted prejudices on the part of men who strongly dissented from Dr. Elliotson's views on certain subjects. In spite of these obstacles, however, its reception has been more flattering than we dared to anticipate. The first impression was rapidly exhausted; it became the favourite class-book in the majority of our Medical Schools; and even those who were formerly strongly prejudiced against it, have since acknowledged the practical information they have derived from its perusal. All this is highly satisfactory; and were any additional proof of its sterling worth required, it would be furnished by the fact that the Germans have published a translation.

In entering on the task of preparing for publication a Second Edition, we have been stimulated by the success of the first to fresh exertions, in order to render it (if possible) still more worthy of the approbation it has received. With a view to the accomplishment of this object, we have ventured on making certain additions and alterations; which, without materially increasing the size of the book, will (as we believe) materially enhance its value. Much care and discrimination were necessary in making these additions,—both as to the *materiel* to be selected, and the mode of its insertion; otherwise the book would have been injured, rather than improved. We have therefore been careful only to remedy obvious deficiencies, and to make such other additions as more recent researches had rendered necessary. The sources whence this supplementary matter has been taken are various; but we have of course been guided, to a great extent, by public opinion;—making our selections from those works which seemed best entitled to our confidence, for their general accuracy and soundness of doctrine. For the purpose of rendering these additions as useful as possible, it has been deemed advisable to insert them within brackets, in the text; taking care, however, to preserve the continuity of the whole; and to acknowledge, in a foot-note, the source whence each quotation was derived. Some other illustrative extracts, often very interesting in a literary point of view, and all bearing on some medical observations in the text, have been inserted as foot-notes.

The alterations that have been made, though few, are such as have

been dictated by a desire to consult the convenience of the Reader. The subjects have been grouped together, in conformity with Dr. Elliotson's own views; and divided into Parts, Books, Chapters, and Sections. Page-headings and side-titles have been introduced; and, together with a copious Index, will (it is hoped) enable the Reader to refer to any particular passage with perfect ease.

These are the alterations we have deemed it necessary to make. In the performance of our task, we have been actuated (at every step) by a sincere and ardent wish to render the volume worthy of the reputation which Dr. Elliotson has so justly acquired, both as a teacher and Physician. In working out this design, we have received every assistance from the enterprising publisher, who has spared no expense either in the literary or the printing department;—being anxious to raise this distinguished member of his series of Medical Text-Books to a degree of excellence commensurate with the favour it has received. Whatever approbation or censure may be bestowed on our labours as Editors, we feel quite certain that the valuable materials contained in this book, will always meet with the respectful consideration due to genius and industry, when directed to the alleviation of human misery.

## PREFACE OF THE AMERICAN EDITOR.

---

In the last London edition of Dr. Elliotson's Lectures, numerous additions have been made, with the view of giving to the work the character of a complete Treatise on the Practice of Medicine, suited to the purposes of a text-book. Most of these have been retained, whilst at the same time the work has been still further enlarged. In particular, it has been thought necessary to give a more extended space to the consideration of Remittent and Yellow Fevers, which, as the reader will observe, are but cursorily treated of by Dr. Elliotson. A separate article, by the American editor, has therefore been devoted to each of these affections. His other additions, with the exception of a few foot notes, are included within brackets, and bear his initials.

THE  
PRINCIPLES AND PRACTICE  
OF  
M E D I C I N E.

INTRODUCTION.

THE Art of Medicine is to be perfected, I conceive, by improvements in our knowledge of the nature of diseases, by improvements in diagnosis, and by improvements in our acquaintance with remedies and their application.

*Anatomy.*—Improvements in our knowledge of the nature of diseases must be obtained through the cultivation of Anatomy and Physiology, and of Morbid Anatomy and Morbid Physiology; or, in other words, from an acquaintance with the derangements that take place in structure and function. It is evident that no one can be acquainted with a disease, unless he is acquainted, more or less, with the part diseased,—its situation, form and structure; and the more accurate and minute his acquaintance with these, the greater, *cæteris paribus*, will generally be his knowledge of the nature of its lesions. I say "*cæteris paribus*;" because a knowledge of mere Anatomy, however accurate and minute, does not imply a knowledge of disease (its symptoms, history, and causes), or skill in treating it;—any more than a knowledge of the alphabet, and the ability to read, imply a literary character: and nothing can be more absurd than for the public to presume that a man is a good practitioner, *merely* because he is a good anatomist. An anatomist is not necessarily even a physiologist; and Mery was accustomed to say,—“We anatomists are like the porters of Paris; who are all well acquainted with all its streets, as well as all its lanes and alleys, but know nothing of what passes within the houses.”<sup>a</sup> The most assiduous examination of only the dead body, can disclose but little of the functions and properties of the living. The structure of the brain would never teach us that it is the organ of feeling and thought; or of the kidney, that it produces a fluid containing lithic acid and urea. The sympathy existing between the nasal membrane and diaphragm, and between the kidneys and surface; the curious phenomena resulting from contagions and malaria; the various morbid actions to which various parts are liable (the innumerable diseases of the nervous system, for instance); the susceptibility of various parts to the operation of various agents during health (such as of the mouth to the operation of mercury, and of the stomach to that of ipecacuanha); the peculiar power of certain substances over certain diseases (as of quina over intermittent fever);—all this would never be suspected at the dissecting-table. And I cannot refrain from remarking, that for any one to pride himself upon his knowledge of established Anatomy, would be exceedingly weak; as it requires no preparatory philosophical education, and no in-

<sup>a</sup>Rees's Cyclopædia; Article “Mery.”

tellectual exertion; but merely the possession of eyes and memory, and a willingness to employ them. Dr. McCulloch, in his powerful, though (I must be pardoned in saying) occasionally extravagant, work, apologizes for not arranging his cases anatomically; on the ground that it would have savoured of pedantry;—"a small pedantry," he says, "far too common; as if any man could not make himself master of Human Anatomy in a few weeks, as well as of any other tangible and demonstrable substances."<sup>a</sup> But if it would be laughable for any one to pride himself on his knowledge of Anatomy, it is culpable in a physician not to be a good anatomist. Otherwise he cannot comprehend the phenomena of many diseases. He cannot, for example, understand why, in partial paralysis of the head, sometimes only certain muscles cease to obey the will;—why loss of sensation sometimes occurs alone, and why to only a certain extent;—why the pain of the neuralgia takes a particular course;—or why, in disease of the heart, unusual varieties of sound and impulse are observable in particular portions of the cardiac region. He cannot possess any but the most superficial knowledge of Morbid Anatomy; the cultivation of the far greater and more important part of which is peculiarly the duty of the physician, who treats the chief morbid states of the most important organs of the body; and not of the surgeon, who does not even witness their symptoms. He will, therefore, either neglect to complete the investigation of his unsuccessful cases, by examination after death, or be unable to appreciate what presents itself, and perhaps be indebted to an active surgeon for information. He cannot otherwise be a good physiologist; for, although Anatomy alone will seldom teach the operations of an organ, these can manifestly not be known, unless the organ itself is understood.

*Physiology.*—The importance of Physiology requires no argument in its support; for, except in obvious structural or mechanical changes, the symptoms of disease are chiefly Morbid Physiology; and therefore, to quote the familiar passage of Galen,—"The magnitude of a disease is proportionate to its deviation from the natural state; and he only knows the extent of the deviation who knows exactly what is the natural state." Εἰς ὅσον γὰρ ἐξίσταται τῆς φύσεως ἕκαστον, εἰς τοσούτο καὶ μεγέθους ἤκει. Τὸ δ' ὅσον ἐξίσταται, γινώσκει μόνος τῷ κατὰ φύσιν, ἀκριβῶς ἐπισταμένῳ.<sup>b</sup> And again, Μὴ δύνασθαι τίνα καλῶς ἰάσασθαι τὰ νοσήματα, πρὶν ὅλου τοῦ σώματος ἐπιστάσασθαι τὴν φύσιν.<sup>c</sup> Without a thorough acquaintance with both the natural structure and the functions, a thousand highly interesting deviations will never be recognised in the cases which come daily before us.

*Pathology.*—If such is the importance of Anatomy and Physiology to every physician, it will not be disputed that, in order to advance our knowledge of the nature of diseases, these sciences should be improved to the utmost. But however necessary these foundations (Anatomy and Physiology), the grand source of this knowledge is the observation of the phenomena of diseases,—their symptoms, history, and causes (in other words, Pathology), and of their structural lesions (in other words, Morbid Anatomy). No one expresses a doubt respecting the importance of Pathology;—the importance of observing the symptoms, and tracing the history of diseases; and of investigating their peculiarities, analogies, and causes. Yet, in all this, how liable are we to error! How patient and searching an eye is required to note all the phenomena of a disease;—to perceive what is essential to its existence, and what is only incidental! How profound a judgment to reason upon these phenomena, and to investigate their causes;—to discern the analogies between affections which, at first sight, are perfectly distinct! And, at the same time, how cool should be the judgment duly to appreciate all fanciful analogies, all

<sup>a</sup> "Marsh Fever and Neuralgia;" Volume 2; Page 104.

<sup>b</sup> "As is the degree of deviation from nature, so is the magnitude at which the disease arrives; but the amount of this derangement can be ascertained only by him who is accurately acquainted with the natural state."—"Methodus Medendi ad Glauconem;" Liber 1; Caput 1.

<sup>c</sup> "It is impossible for any one to cure diseases perfectly, without having previously well examined the constitution of the whole body."—"Methodus Medendi;" Liber 1; Caput 1.

hypothetical suggestions! Exactly the same difficulties surround Morbid Anatomy; but in its case they are alleged, by some, as objections to its prosecution. But how could any affection beneath the surface of the body have been understood, without an ocular investigation of the parts affected? How could pain in the chest, dyspnœa, cough, and pyrexia, have been known as signs of inflammation of the lungs or their membranes, unless the examination of persons who died under these symptoms, had proved such a lesion to be frequently their cause? If knowledge can be thus obtained, why not obtain the utmost possible? True it is, that incidental morbid appearances have often been mistaken as necessary and constant; and that some even pretty constant appearances have often been absurdly announced as the essence of the disease, when they were merely its effect, or (at the utmost) only among the number of its phenomena. Equally true it is, that changes after death have been mistaken for morbid appearances; as was pointed out by Dr. John Davy in the case of redness from inhibition of blood.<sup>a</sup> But such errors, surely, afford no reason for neglecting careful and extensive examinations of diseased parts, and drawing just inferences as to the connection of the change of colour or structure with the disease;—they supply no reason for not cultivating so ample a field of knowledge scientifically. If a disease be accompanied by a change of structure or appearance *within* the body, surely this change, as a fact in the disease, is worthy of notice;—as worthy as *visible* changes in the skin, the mouth, or the eyes; which changes are always carefully described by these objectors, even when merely secondary effects; though they differ from the facts of Morbid Anatomy, only in the accident of being cognisable without dissection; while they are not a whit more necessary to a perfect history of a disease, and are much less in number;—owing to the circumstance of nearly all our organs being concealed from view. After some diseases, indeed, no change of structure or appearance is discernible. But even here, extensive anatomical investigation is important; for it often prevents us from forming groundless hypotheses, as to the seat and nature of such affections. Hydrophobia might be referred to the stomach, were it not that the red patches, which are sometimes seen in this organ after the disease, are frequently not to be detected. Tetanus might be thought always to arise from inflammation of the spinal marrow, were not this part frequently found free from inflammation in tetanic patients. It discloses to us a fact which we might otherwise have doubted;—that diseases may be only functional, as well as structural;—that, in the words of one of the most intelligent and industrious cultivators of Pathology and Morbid Anatomy (Dr. Andral), —“it is one of the most serious errors to which the ill-directed study of Morbid Anatomy can lead, to admit no other alteration in the economy, than those which are discoverable by the scalpel.”<sup>b</sup> We learn, in short, to form a just estimate of Morbid Anatomy:—that it is an important part of the basis, but by no means the “*main basis*” of Pathology.

*Diagnosis of Diseases.*—But if our art is to be perfected by a better acquaintance with the nature of diseases, it is not less to be perfected by improvements in distinguishing them;—by improvements in diagnosis.<sup>c</sup> The diseases of the lungs and their membranes, are as well understood as any of the body; yet the best practitioners continually fail in distinguishing them. They often fail, for instance, to distinguish one form of chronic bronchitis from hydrothorax; the treatment of which diseases may be totally different. So important is diagnosis, that it has become a proverbial saying,—“The knowledge of a disease is half the cure.” Diagnosis also

<sup>a</sup> “Transactions of the Medical and Chirurgical Society of London;” Volume 10; Page 89.

<sup>b</sup> “Clinique Medicale;” Tome 3; Page 510.

<sup>c</sup> On this subject we beg to refer the reader to Dr. Marshall Hall’s “Treatise on Diagnosis.” It is now incorporated with his “Principles of the Theory and Practice of Medicine.” Dr. Cowan, in his “Beside Manual of Physical Diagnosis,” has given, in a very portable form, the physical signs of the diseases which affect the following important parts:—1. Lungs and Pleura. 2. Heart and Pericardium. 3. Vascular System. 4. Abdomen, Osseous System, and Auditory Apparatus. The physical signs are chiefly furnished by auscultation and percussion.

is to be improved, not only by a better acquaintance with the symptoms and history of diseases, but by a better acquaintance with Morbid Anatomy; so that the correspondence between symptoms and local lesions may be established, and thus the affection clearly ascertained. As *Healthy Anatomy* is the foundation of *Morbid Anatomy*, and *Physiology* is the foundation of *Pathology*, the importance of these also to improvements in diagnosis is apparent.

*Laennec's Discoveries.*—The discoveries made by Laennec with respect to diseases of the heart and lungs,<sup>a</sup> are great enough to entitle him to all the honours which have ever been acquired in our profession. He has enabled us to judge of diseases, which are otherwise often not distinguishable with certainty, or even at all; and this with an accuracy inconceivable to those who are unacquainted with his investigations. He has enabled us to distinguish diseases of the heart, which were formerly, and are still, too often either all expressed by the easy term—"disease of the heart,"—without any specification of the part of this complicated organ affected; or are as often passed over entirely;—the case being mistaken for hydrothorax, or some pulmonary affection. He has also enabled us to distinguish diseases of the lungs which, in many cases, could not be pronounced upon with accuracy; and others of which the diagnosis was always uncertain. Moreover, we can point out the very part affected.

But Laennec's discoveries are objected to on the very ground of their accuracy. We are asked—"Cui bono?" ("Of what use are they?") The answer is plain. It is universally allowed that every disease should be described, and its nature ascertained, as accurately as possible. Now, with every advance in accuracy of description, and in knowledge of the source of symptoms, diagnosis imperceptibly and inevitably becomes more accurate. To condemn accurate *diagnosis*, therefore, is to condemn accurate *knowledge*;—to rest satisfied with imperfect information, when industry would give us more;—to admire ignorance, when knowledge is within our reach.

The art of diagnosis ought to be universally cultivated, without reference to its utility in particular instances. It is part of our science; every part must be cultivated for the perfection of the whole; and what may not be practically useful to-day, may become so to-morrow. How many discoveries in Chemistry and Physics appeared, at first, to be objects of mere curiosity; but have afterwards been applied to the most important purposes! Plato possessed so exalted a feeling for science on its own account, that he considered the applications of geometry to practical purposes, as far inferior to its philosophy;<sup>b</sup> and those who may see no reason for being so deeply enamoured of science as that, must allow that there is every reason to remember the words of Jesus, the son of Sirach:—"None may say—'What is this?'—Wherefore is that?'—for, at time convenient, they shall all be sought out."<sup>c</sup> In improving diagnosis, it is impossible to discover only what is obviously useful. The research must be made generally; and what is at once useful, and what is not, must turn up together. In the diseases of other organs, we always aim at accuracy of diagnosis, without any hope of utility. When a solid tumour exists in the abdomen, we endeavour to ascertain whether it is the liver, the

<sup>a</sup> See his celebrated Treatise, entitled—"De l'Auscultation Mediate; ou Traité du Diagnostic des Maladies des Poumons et du Cœur; fondé principalement sur ce Nouveau Moyen d'Exploration." ("Treatise on the Diagnosis of Diseases of the Lungs and Heart; chiefly founded on a New Mode of Investigation,—Mediate Auscultation.") This work is principally known to the English reader through the medium of Dr. Forbes's Translation;—a work which is enriched with many valuable notes.

<sup>b</sup> Οὐδὲν εἰ μὲν οὐτὼν ἀναγκάζει θεάσασθαι, προσήκει, εἰ δὲ γένεσιν, οὐ προσήκει. ὡς γὰρ πράττοντες τε καὶ πράττειν ἐνεκα πάντας τοὺς λόγους ποιούμενοί τε λόγουσι, τετραγωνίζεις τε καὶ παρατείνεις καὶ προστιθεῖναι, καὶ πάντα οὗτω φεγγόμενοι· τὸ δ' ἐστὶ πῶς τὰν τὸ μάθημα γνώσεως ἐνεκα ἐπιτηδεύμενον.—ΠΟΛΙΤΕΙΑ. Liber vii. ("We must not, therefore, if compelled to contemplate, on the one hand, an actual being, say—'It is fitting;' and if we contemplate, on the one hand, the origin of that being, say—'It is not fitting;' for they speak as intriguing advocates, who utter all their speeches with a sinister design,—squaring, stretching, adding, and asseverating without scruple; but every scientific pursuit is cultivated for the sake of knowledge.")

<sup>c</sup> "Ecclesiasticus;" Chapter 39; Verse 17.

spleen, the pylorus, an ovarium, a new formation, or something else; although the treatment would probably be the same in all.

*Auscultation and Percussion.*—But there is immediate utility in the discoveries of Avenbrugger<sup>a</sup> and Laennec. No one will pretend that, in chronic diseases of the chest—with the exception, perhaps, of phthisis—the diagnosis is generally satisfactory. Before I adopted auscultation, I frequently discovered disease of the heart after death, where I had not previously suspected it; and frequently found the organ sound, when I had supposed it diseased. When I was correct in expecting to see organic affection of the heart, I was often wrong as to the precise nature of the lesion. Too often has auscultation at once revealed to me disease of the heart, when, by good practitioners, no affection of the heart, or even of the chest, had been suspected; or where the case had been named “nervous palpitation” or “asthma;”—where the lungs had been regarded as the seat of the malady; or where the case had been treated with the most violent remedies for hydrothorax. Repeatedly have I seen chronic bronchitis with extreme congestion in the lungs mistaken for hydrothorax; and this was unavoidable, when percussion and auscultation were omitted: because the symptoms were precisely the same, with the exception of those which percussion and auscultation could alone disclose. Inflammation of the substance of the lungs often takes place during other diseases, without being obvious before death to any but the auscultator and percussor. Without the aid of the ear, who can distinguish emphysema of the lungs, or, in every case, pneumato-thorax?<sup>b</sup> Both may be readily mistaken for hydrothorax. The symptoms may be a pallid face, purple lips, orthopnoea, sudden starting from sleep to the waking state, a small and intermitting pulse, cold extremities, and swollen feet. The remedies of hydrothorax may appear indicated; but the ear will discover, on percussion, a hollow sound—far too hollow a sound—in the chest, at its very lowest parts; while there is, in the first case, little respiratory murmur, and in the second none at all,—at the very place where the hollow sound is heard. Nothing but the ear can show the nature of these cases. Nothing but the ear can distinguish them from each other. Without the ear, no case can be known with certainty to be one of hydrothorax,—however marked the symptoms.

It has more than once happened to me, to be unable to form any opinion as to the nature of a disease, without auricular examination. Patients have complained of mere debility and loss of flesh, with slight general ailment; and have declared themselves free from all local symptoms:—so that nothing but the most random guess could be made at their disease. A minute examination of them has discovered nothing wrong, or nothing *materially* wrong, in the performance of the functions of the head, chest, or abdomen; but, on percussing the chest, the sound proved as dead in some part as if the thigh had been struck; and, applying the stethoscope, no respiration has been heard, or the voice has rushed through the instrument, or an unnatural sound has been heard in the heart; and thus the whole mystery has been at once cleared up. In truth, the exact state of the functions of the lungs and heart cannot be ascertained, except by the ear; and without an examination by its aid, no one is warranted in declaring these functions healthy. I once

<sup>a</sup> Avenbrugger's discovery was percussion; and his work on that subject, first given to the world in 1761, was entitled—“*Inventum Novum, ex Percussione Thoracis Humani, ut Signo, Abstrusos Interni Pectoris Morbos Detegenti.*” (“A new Discovery for detecting Obscure Diseases of the Chest, by means of Percussion.”) A translation of it is given in “Original Cases, with Dissections and Observations, illustrating the Use of the Stethoscope and Percussion in the Diagnosis of Diseases of the Chest. By John Forbes, M. D., Physician to the Chichester Dispensary.”

<sup>b</sup> The name “*pneumo-thorax*,” adopted from Itard by Laennec, is evidently improper. Such compound words are always made from the dative singular,—the final letter being changed into *o*, if it be any other vowel. We thus have “*utero-gestation*,” “*cerebro-spinal*,” and “*hemato-cele*.” The genitive and dative of αἷμα (*blood*) are αἵματος, αἵματι. The genitive and dative of πνεῦμα (*air*) are πνεύματος, πνεύματι; and the compound word should be “*pneumatō-thorax*.” Indeed, we already have “*pneumatompholos*,” to signify a person with an umbilical hernia; and, what is still closer, we have the word “*pneumatocèle*.”

admitted a man into St. Thomas's Hospital, without any friend to give an account of him; and so deaf and stupid, that he could scarcely give any himself. He complained merely of occasional coldness, heat, and sweating, with debility; declared he had been ill but two or three weeks; and ascribed his complaint to sleeping in a damp bed at Gravesend. The case resembled remittent fever more than any thing else; and I treated it with sulphate of quinine. The symptoms of remittent fever yielded; but the debility remained, and even increased. I investigated the case minutely. There were no symptoms of phthisis, or of any other local disease, except convexity of the nails; but, on striking the chest, I found the right superior part give a dead sound; and in the centre of this I heard pectoriloquism. The case was then regarded as one of abundant tubercular deposition in the right lung, with an excavation in its centre; and the autopsy showed that the diagnosis was correct. The diagnosis, it is true, did not lead to a cure; but it prevented me from plaguing the patient with medicines, from an erroneous idea of the nature and seat of the disease; and it enabled me to give a correct prognosis. Even when there can exist no doubt in the mind of an able practitioner, as to the seat and nature of the disease, auscultation may prove a useful aid. In consultation, another practitioner, from a peculiar bias towards the heart, may consider the symptoms to arise from that organ; although they are evidently palmonic, perhaps even phthisical; and *vice versa*. Or perhaps he may refer unquestionable symptoms of organic pectoral disease in general, to the liver, or the digestive organs (according to the reigning folly of the day); as is done, continually, with affections of the head and spine. It may be impossible clearly to refute him by the ordinary means of diagnosis; and yet auscultation may furnish some symptoms so decisive as to silence him.

Auscultation, however, can never justify us in the least neglect of the general symptoms and history of a disease. This would indeed be unphilosophical; for the symptoms of auscultation, are but one set among a number of others. But if it would be unphilosophical to neglect the general symptoms, it would be equally so to despise those which present themselves to the ear. If the functions of the heart and lungs are naturally performed with peculiar sounds, and if in diseases the sounds are altered, these deviations surely demand equal attention with those which are discernible by the other senses. Surely the physician requires all his senses for the acquisition of knowledge; as much as other prosecutors of natural science. We employ our eyes to discern the countenance and general aspect of our patients; the changes of the pectoral, intestinal, and renal secretions; and alterations in the colour, size, and figure of various parts. We employ our touch to examine the pulse; and to ascertain the preternatural presence of fluid, preternatural enlargement, diminution, or induration. Our smell gives us information as to the depraved secretions of fever, as to suppuration, and as to gangrene. In diabetes, some have even recourse to the sense of taste. Nay, certain symptoms observable by the ear only, are always carefully dwelt upon. Borborygmi, for instance, enter into the definition of hysteria; and all the varieties of cough and wheezing are described. Why, then, should such sounds as are elicited by striking the chest, or require the ear to be brought either into contact with it, or into connection with it by means of a solid medium, be despised? The celebrated Hook not only did not despise the ear as an inlet of knowledge, but looked forward to the invention of acoustic instruments, which would enable it to make important discoveries. Indeed, he almost prophesied the stethoscope. "There may be a possibility," says he, "of discovering the internal motions and actions of bodies by the sound they make. Who knows but that, as in a watch we may hear the beating of the balance, and the running of the wheels, and the striking of the hammers, and the grating of the teeth, and multitudes of other noises,—who knows, I say, but that it may be possible to discover the motions of the internal parts of bodies (whether animal, vegetable, or mineral) by the sound they make;—that one may discover the works performed in the several offices and shops of a man's body; and thereby discover what engine is out of order, what works are going on at several times, and lie still at others, and the like. I could proceed further; but methinks I could hardly for-

bear to blush, when I consider how the most part of men will look upon this. But yet, again, I have this encouragement;—not to think all these things utterly impossible, though never so much derided by the generality of men, and never so seemingly mad, foolish, and fantastic;—that, as the thinking them impossible cannot much improve my knowledge, so the believing them possible may perhaps be an occasion for taking notice of such things as another would pass by without regard, as useless. And somewhat more of encouragement I have also from experience;—that I have been able to hear, very plainly, the beating of a man's heart; and 'tis common to hear the motion of the wind, to and fro, in the guts and other small vessels. The stopping in the lungs is easily discovered by the wheezing. As to the motion of the parts one amongst another, [in order] to their becoming sensible, they require either that their motions be increased, or that the organ [of hearing] be made more nice and powerful, to sensate and distinguish them as they are; for the doing of both which, I think it not impossible but that, in many cases, there may be helps found.<sup>a</sup>

Far be it from the defenders of auscultation and percussion to assert, that the diagnosis of thoracic diseases can never be doubtful. Skill in auscultation requires much application; and, even with the greatest, doubt will frequently exist. The stethoscope does not render the parietes of the chest transparent. Percussion and auscultation merely open a new set of symptoms to our notice; and, as diagnosis is certain in proportion to the number and nature of the facts on which it is founded, and the percussor and auscultator, with all the same means of judging as his opponents, possesses others in addition, he is better qualified to form an opinion; and, though he may sometimes still regret his want of certainty, he knows that by shutting his ears,—by levelling himself with his opponents, he augments his uncertainty a hundred-fold.<sup>b</sup>

The alleged errors of those who practise auscultation, are no arguments against it. Many tales of this description, like those of the errors of phrenologists, have, when traced to their origin, proved inaccurate, or even altogether destitute of truth; and eagerly to catch at them would betray a mind hoping that no fresh knowledge is to be attained. Persons, it must be remembered, who have no skill will pretend to it; and the skilful will sometimes give a hasty judgment; but, as in the case of Phrenology, nature is open to us all. Let us examine for ourselves—examine carefully and patiently;—not anxious to find auscultation a deception, but hoping to find the promise of new information fulfilled;—not unwilling to learn because we are no longer *in statu pupillari* (“in the rank of pupils”);—not so high in our own estimation, as to feel indisposed to be taught by others;—not unphilosophical enough to have a hostile opinion upon a matter which observation must decide;—not guilty of the inconsistency of lamenting the imperfection of our art, and whining about its sad claim to the title of a conjectural art, while we are too indolent to investigate a method which professes to remove much of its uncertainty, is recommended by men of the greatest talent and the most intense application to the study of their profession, bears upon itself the stamp of probability, and the results of which are capable of being proved physically necessary.<sup>c</sup>

<sup>a</sup> “Method of improving Natural Philosophy.” Posthumous Works; Page 39.

<sup>b</sup> Dr. Andral—who nowhere shows a disposition to overrate the value of auscultation, and is a highly-informed practical physician of the soundest judgment—says, in the preface to the second part of his “Clinique Médicale,”—“Thanks especially to the wonderful discovery of Professor Laennec, the diagnosis of a great number of thoracic affections may be frequently established with as much accuracy as that of the least complicated luxation, or the simplest fracture. There is a certain number of pneumonic inflammations, in which we are able to follow the different phases of the alteration of the lungs, and their return to the healthy state, with as strict precision as the eye externally follows the different periods of the cicatrization of a wound. There are affections of the heart, in which the nature of the organic lesion may be determined by the sense of hearing, almost as accurately as the state of a cutaneous tumour may be ascertained by the eye, or the state of the neck of the womb by the touch. Clinical observation, however, meets with many cases in which diagnosis is very obscure; and others, in which the very nature of the affection is still a matter of dispute.”

<sup>c</sup> I said, upon another occasion, that “the greatest discoveries have generally been at first

*Therapeutics.*—With respect to the third mode in which I conceive that our art must be perfected,—improvements in our knowledge of remedies and their application,—I must be brief. Much remains to be accomplished in the discovery, both of the virtues of medicines already in use, and of new medicines, or such modifi-

riculed, and their authors, no less than all the truest benefactors of the human race, have been ‘despised and rejected of men.’ (‘Prophecies of Isaiah,’ Chapter 53; Verse 3.)

‘Romulus, et Liber Pater, et cum Castore Pollux,  
Dum terras hominumque colunt genus, aspera bella,  
Componunt, agros assignant, oppida condunt,  
Ploravère suis non respondere favorem  
Speratum meritis.’

(‘Romulus, and Bacchus, and Castor, and Pollux, while dwelling among men, brought to a successful issue many difficult wars, distributed territories, and built cities; but they found that the gratitude excited, was not equal to the benefits conferred.’—*Horace’s ‘Epistles,’ Book 2; Epistle 1; Lines 5, 7, 8, 9, and 10.*)

“Let us remember that Harvey, whose memory *we* honour, was dishonoured at first by his cotemporaries, for the discovery which immortalized his name;—that he lost his practice, and—so far from finding comfort among his brethren—left the country, and was lanpooned from one end of Europe to the other; and that no English physician who had attained the age of forty at the time, ever (to the end of life) acknowledged the circulation of the blood. Let us remember that Sydenham, whose memory also *we* honour, was called a quack and a murderer by many of his cotemporaries; whose names, whatever bustle they made during their existence, have never once been mentioned since their death. Let us remember that the discovery of the lacteals was at first rejected with contempt;—that Bartholin, in a letter, says,—‘There is not one among the doctors of Montpellier who acknowledges the lacteal vessels;—so wedded are they to the authority of Galen; for which they contend as though ‘pro aris et focis’ (‘for their altars and homes,’) and disregard the experiments of the moderns.’ Let us remember that even old Harvey, when the thoracic duct was afterwards discovered, could not at once loosen himself from the bonds of early prejudice, and give up the prevailing belief that the lacteals all terminated in the liver; and that the very Bartholin who saw the folly of the Montpellier doctors, never believed in the exclusive office of the thoracic duct. Let us remember that, if the illustrious father of our modern philosophy, Lord Bacon, was not vilified and imprisoned (like Galileo) for announcing truth, he was represented by Cecil to Elizabeth, when she thought of making him her Solicitor-General, as ‘a man of mere speculation;’—as one wholly given up to philosophical inquiries, —*new*, indeed, and *amusing*; but *fanciful* and *unsound*; and therefore more likely to distract her affairs, than to serve her carefully and with proper judgment.’

“In ancient times, Horace saw his odes despised, because they were *new*. The public, he said,—

——‘Nisi quæ terris semota, suisque  
Temporibus defuncta videt, fastidit, et odit.’

(‘Neglects and dislikes every thing which does not relate to times long since passed away.’—*Horace’s ‘Epistles,’ Book 2; Epistle 1; Lines 21 and 22.*)

‘Est vetus atque probus, centum qui perficit annos.’

(‘He is ancient and excellent who has been dead a hundred years.’—*Horace’s ‘Epistles,’ Book 2; Epistle 1; Line 39.*)

“But, like the illustrious Gall, Laennec is no more:—

‘Extinctus amabitur idem.’

(‘He himself, when dead, will be beloved.’—*Horace’s ‘Epistles,’ Book 2; Epistle 1; Line 14.*)”

I cannot forbear from making the following extract from the first volume of Gall’s work “sur les Fonctions du Cerveau:”—

“The followers of the different schools of philosophy among the Greeks, accused each other of impiety and perjury. The people, in their turn, detested the philosophers; and accused those who investigated principles, with presumptuously encroaching upon the rights of the Deity. The novelty of Pythagoras’s opinions caused his banishment from Athens; those of Anaxagoras threw him into prison; the Abderites treated Democritus as a madman, because he dissected dead bodies, in order to discover the cause of insanity; and Socrates, for demonstrating the unity of God, was condemned to drink hemlock.

“The same scandal has been renewed at all times, and in all nations. Many of those who, in the fourteenth century, distinguished themselves by their knowledge of natural things, were put to death as magicians. Galileo, for proving the earth’s motion, was imprisoned at the age of seventy. Those who first maintained the influence of climate upon the intellectual character of nations, were suspected of materialism.

cations of old ones as almost entitle them to the epithet "new." Every advance in our knowledge of the essential nature of diseases, will (no doubt) enable us to improve our application of remedies upon general principles;—to improve our "general indications." But without any additional knowledge of the nature of diseases, cautious trials—guided by the best analogy we may discern, or by some fortuitous occurrence—will enable us (if we are disposed to labour) to effect much in extending our knowledge of the powers of particular remedies over particular diseases. Lord Bacon<sup>a</sup> regrets that physicians apply themselves so exclusively to

"Universally, nature treats new truths and their discoverers in a singular but uniform manner. With what indignation and animosity have the greatest benefits been rejected! We may instance potatoes, Peruvian bark, vaccination, &c. As soon as Varolius made his anatomical discoveries, he was decried by Sylvius as the most infamous and ignorant madman. *Vesanium, litterarum imperitissimum, arrogantissimum, calumniatorem maledicentissimum, rerum omnium ignarissimum, transfugam, impium, ingratum, monstrum ignorantia, impietatis exemplar perniciosissimum, quod pestilentiali halitu Europam venenat, &c.* ('Mad, very deficient in learning, most arrogant, most slanderous calumniator, ignorant of every thing, a turn-coat, impious, ungrateful, a monster of ignorance, a most pernicious example of impiety, which poisons Europe with its pestilential breath,' &c.) Varolius was reproached with dazzling his auditors by a seductive eloquence; and with artificially effecting the prolongation of the optic nerves as far as the thalami. Harvey, for maintaining the circulation of the blood, was treated as a visionary; and depravity went so far as to attempt his ruin with James and Charles the First. When it was no longer possible to shorten the optic nerve, or to arrest the course of the blood in its vessels, the honour of these discoveries was all at once given to Hippocrates. The physical truths announced by Linnæus, Buffon, the pious philosopher Bonnet, and George Le Roy, were represented as impieties likely to ruin religion and morality. Even the virtuous and generous Lavater was treated as a fatalist and materialist. Everywhere do fatalism and materialism, placed before the sanctuary of truth, make the world retire. Everywhere do those upon whose judgment the public relies, not merely ascribe to the author of a discovery the absurdities of their own prejudices; but they even renounce established truths, if contrary to their purposes; and revive ancient errors, if calculated to ruin the man who is in their way.

"This is a faithful picture of what has happened to me. I have, therefore, some reason to be proud of having experienced the same lot as men to whom the world is indebted for so great a mass of knowledge. It seems that nature has subjected all truths to persecution, in order to establish them the more firmly; for he who can snatch one from her, always presents a front of brass to the darts hurled against him, and has always force enough to defend and establish it. History shows us that all the efforts and sophisms which are directed against a truth once drawn from darkness, fall like dust blown by the winds against a rock.

"The instances of Aristotle and Descartes should particularly be quoted, when we wish to display the influence of prejudice upon the good or bad fortune of new doctrines. The opponents of Aristotle burnt his books. Afterwards, however, the books of Ramus, who had written against Aristotle, were burnt; the opponents of the philosopher of Stagira were declared heretics; and it was even forbidden by law to dispute his doctrines, under pain of being sent to the galleys. There is now no longer any discussion about the philosophy of Aristotle. Descartes was persecuted because he taught the innateness of ideas; and the University of Paris burnt his books. He had written the most sublime thoughts upon the existence of God; but Voët, his enemy, accused him of atheism. Afterwards, this same university declared itself in favour of innate ideas; and when Locke and Condillac attacked innate ideas, the cry of materialism and fatalism resounded on all sides.

"Thus, the same opinions have at one time been regarded as dangerous because they were new, and at another as useful because they were ancient. We must, therefore, pity mankind; and conclude that the opinions of cotemporaries as to the truth or error, and dangerous or innocent tendencies of a doctrine, are very suspicious; and that the author of a discovery should be anxious only to ascertain whether he has really discovered a truth or not." (Page 221.)

Gall might have added, in the words of Professor Playfair, that—"notwithstanding "the splendour of Newton's discoveries, the beauty, the simplicity, and grandeur of the system they unfolded, and the demonstrative evidence by which that system was supported—the Cartesian system of vortices kept its ground for *more than thirty years* after the publication of those discoveries;" and that actually "the Newtonian philosophy first entered the University of Cambridge under the protection of the Cartesian," by a stratagem on the part of Dr. Samuel Clark; who quietly explained the views of Newton, without any appearance of argument or controversy, in the form of notes to a new translation which he published of the French Cartesian work, long established as a text-book by the tutors of the University.

Dr. Chambers, speaking of the first reception of the Newtonian philosophy, says—"authority scowled upon it, taste was disgusted by it, and fashion was ashamed of it."

<sup>a</sup> "Instauratio Magna."—First Part.

general indications;—neglecting the peculiar properties of remedies in particular diseases. “Medici hujusce ætatis,” he says, “licet generales intentiones curationum non malè persequantur; particulares tamen medicinas quæ ad curationes morborum singulorum proprietate quâdam spectant, aut non benè norunt, aut non religiòse observant.”<sup>a</sup> He remarks that they merely go on, in their prescriptions, “addendo, et demendo, et mutando, circa medicinas, prout iis libitum fuerit; et ferè, pharmacopœorum more, quid pro quo substituendo;”<sup>b</sup> and he advises that some physicians “et eruditione et practicâ insignes, opus aliquod conficiant de medicinis probatis et experimentalibus ad morbos particulares.”<sup>c</sup>

Such experimental facts, however insulated they may at first appear, gradually arrange themselves with others into general principles; and thus what is, at first, little better than empiricism, becomes science. I confess that I look with more hope to this source of improvement, than to any other.<sup>d</sup>

*Medical Education in England.*—From the want of a University, Medicine and Surgery were, for a long time, scarcely taught in London at all;—notwithstanding the ample means presented by the population and the hospitals. The student was compelled to travel to France, Holland, Italy, or (in later times) to Germany or Scotland, for the purpose of acquiring a true professional education; for our own two Universities neglected almost entirely to teach medicine. It is doubtful whether this arose from the want of anatomical and clinical means, the hopelessness of rivalling the great continental and Scottish schools, or the idea that their proper end was to teach general knowledge,—to impart only what all educated persons should know; or from the circumstances mentioned in a powerful and remarkable article upon the Universities of England, in the one hundred and sixth number of the “Edinburgh Review:”—the ascendancy of the Colleges over the University;—the subversion of the professorial system by the tutorial. “Time was,” says the reviewer, “when the Colleges did not exist, and the University was there; and were the

<sup>a</sup> “Physicians of the present day, it is probable, may fulfil the general indications of cure not inefficiently; but the particular medicines which, by some special property, are fitted for the cure of particular diseases, they either do not well know, or do not sufficiently regard.”

<sup>b</sup> “Adding, diminishing, and changing medicines, as freely as possible; and generally, according to the custom of apothecaries, substituting one drug for another of similar value.”

<sup>c</sup> “Eminent both for learning and experience, should prepare a work on the approved and the doubtful medicines, adapted to particular diseases.”

<sup>d</sup> To such investigations, therefore, I have sedulously applied myself; and those of my results which were successful, are before the profession:—I. Cases illustrative of the Efficacy of Hydrocyanic Acid in affections of the Stomach; with a General Report upon its Medical Powers. II. Some Facts respecting the Inertness of ordinary Antimonial Powder. III. The Use of Opium in Diabetes; and the Necessity of Varying the Doses of Medicines, in Various Circumstances. The foregoing were published, in the year 1820, in one octavo volume. IV. Nine Papers, published in the 12th, 13th, 15th, 16th, and 18th volumes of the Medico-Chirurgical Transactions, on the following subjects:—1. The Medical Properties of Quinine (Volume 12, Page 543). 2. The Use of the Sub-Carbonate of Iron in Chorea, and its General Properties (Volume 13, Pages 263 and 464). 3. The use of Sub-Carbonate of Iron in Tetanus (Volume 15, Page 161). 4. The Use of Sulphate of Copper in Chronic Diarrhœa (Volume 13, Page 451). 5. Rupture of the Stomach (Volume 13, Page 26). 6. Fallopian-Tube Pregnancy (Volume 13, Page 51). 7. Glanders communicated from the Horse to the Human Subject (Volume 16, Page 171). 8. The Discharge of Fæty Matters from the Alimentary Canal and Urinary Passages (Volume 18, Page 67). 9. Additional Facts respecting Glanders in the Human Subject (Volume 18, Page 201). V. Lumleyan Lectures on “The Recent Improvements in the Art of Distinguishing the Various Diseases of the Heart.” VI. Two Papers in the “Cyclopædia of Practical Medicine:”—1. Acupuncture (Volume 1, Page 32). 2. Neuralgia (Volume 3, Page 165). VII. A Paper on Acupuncture, in the “Cyclopædia of Practical Surgery” (Volume 1, Page 44).

I make this statement for the purpose of easy reference; as some of my friends wish me to collect into one volume these,—the whole of my professional attempts, except the English edition of Blumenbach's Physiology, and an Introductory Lecture upon State-Medicine [delivered in Mr. Grainger's Theatre, Southwark, on Thursday, November 1, 1821]; and I feel disinclined to follow their advice. [To the above list we may add Dr. Elliotson's Edinburgh Thesis (on Inflammation); his “Address delivered at the Opening of the Medical Session, in the University of London, October 1, 1832;” and a Letter “to the Gentlemen who composed Dr. Elliotson's Class of the Practice of Medicine, in University College.”—(March 4, 1839.)]

Colleges again abolished, the University would remain entire." When "the University was paramount, the cycle of instruction was distributed among a body of teachers, all professedly chosen from merit, and each concentrating his ability on a single object;" and "the whole youth of equal standing in the University, were daily collected into large classes under the same professor;" whereas "the Colleges and Halls are now elevated into so many little Universities;" into which "the students are distributed (with little regard to ability or standing) among some fifty tutors," who are "chosen from the fellows;" notwithstanding that "the fellowships were not founded for the purposes of teaching," and that "the fellow rarely owes his eligibility to merit alone, but, in the immense majority of cases, to fortuitous circumstances."<sup>a</sup>

*Establishment of Medical Lectures in London.*—The opportunities of teaching Anatomy, Surgery, and Medicine, in London, however, became at length too great to be entirely thrown away, and the surgeons of the hospitals began to deliver lectures on Anatomy and Surgery, and afterwards the physicians upon Medicine. These lectures were of limited extent; nor, for a time, were systems of courses delivered,—so as to constitute regular schools. The time, the trouble, and the expense of travelling to a University of medical reputation, rendered the emolument fairly to be expected on establishment in practice too high for the mass of the people to afford; and as population increased, and more practitioners were demanded, home medical instruction was sought after by greater numbers every year;—and this the more, as any one could practise without the license or authority of any University.

*Establishment of Medical Schools.*—The lectures improved, and at length regular schools were established; yet, as they were all private, and could confer no privileges or honours, those who required degrees went to the old celebrated schools; while those whose only resource was the private schools, had too limited pecuniary means to devote much above a year to public study; so that these metropolitan schools remained scanty and superficial. The whole of Anatomy, Physiology, and Morbid Anatomy together, was disposed of in a course of little more than three months; the Practice of Medicine, and the science of Chemistry, each in the same period, with only a lecture of one hour's duration three times a week. Much of General Pathology, and Forensic Medicine, was altogether omitted; the whole of Medical Police likewise, and the literature of the profession, were passed over. It was left for the University of London<sup>b</sup> to be bold enough to establish courses of six months' duration; in which full scope would be afforded to the professors of laying before the student the whole body of medical science; to add the charms of varied illustration; to inculcate important points earnestly and repeatedly; and to introduce the student to an acquaintance with medical literature.

*Advantages of Lectures.*—The mode of instruction by lecture, though by no means sufficient of itself, is in my opinion of high importance. When a whole subject can be taught in a solitary course of lectures, and the exhibition of nothing is required,—so that a mere delivery of statement constitutes the whole task of the professor,—there can be no doubt that a good work, containing all the same information, might be studied in private with equal benefit; and, indeed, with this greater advantage;—that it would probably, after costing less, remain in the possession of the student, to be consulted by him whenever he might think fit. But when a circle of instruction is required,—when the subjects are numerous, and demand many courses of lectures, and many professors,—the student cannot be committed to himself. Without lectures he would become (almost to a certainty) bewildered;—studying at irregular intervals, wandering from one subject to another, and getting little fruit from any; whereas the attendance on various lectures, at stated hours, creates an excitement and an interest, as well as a regularity of habit, which are of incalculable utility.

<sup>a</sup> "Edinburgh Review," June, 1831; Volume 53; Pages 386, 387, 394, and 395.

<sup>b</sup> Now called "University-College."

*Drawings and Specimens.*—In our science and art, however, lectures are, on another account, of superior advantage,—indeed indispensable. One part of the office of every medical lecturer, is to describe objects of sense. The attempt to learn Anatomy, Physiology, Chemistry, Materia Medica, or Botany, would be ridiculous, without the inspection of the material objects, and the principal phenomena. Of the Practice of Medicine and the Practice of Surgery, the same is true. No professor, either of the one or of the other, can give his pupils a full idea of the phenomena of diseases, or of the administration of remedial means, unless he refer to patients exhibiting the various phenomena of disease, and subjected to the exercise of our art. As cases, however, cannot be had at pleasure, so as regularly to illustrate a systematic course of lectures, it is indispensable to deliver the general description and history of diseases and their treatment, in a distinct course; and to afford the illustrations from life in a totally separate manner, as they incidentally present themselves in a collection of patients. It is, therefore, essential that there should be both a general course, and clinical instruction. Yet, in the general course, material illustration is both possible and necessary. Representations of the various morbid changes (by copious and well-executed drawings, engravings, and models), and actual specimens of these changes, and all the material products of disease, it is the duty of a teacher to present and explain; although, when I was a student in Edinburgh, the professor of Medicine never exhibited a single drawing, or a morbid specimen.

*Hospitals and Dispensaries.*—For the other great mode of instruction in the Practice of Medicine and Surgery, an hospital is imperiously necessary. A dispensary must always be a miserable substitute for an hospital. No medical University would grant the decree of Doctor in Medicine, to any who had frequented merely a dispensary. At the latter the majority of patients are so little indisposed, as to be able to go about. When seen, they necessarily pass in rapid review before the practitioner;—giving him an opportunity of showing how practice may be despatched, rather than how disease should be investigated: for if the time demanded for the scientific and patient investigation of each case, and for demonstration and explanation to the pupil, were given, the poor creatures would be compelled to lose, in attending at the charity, far more time than their condition in life or their strength would allow. There is, besides, among the patients of a dispensary, no certainty that medicine is regularly taken;—no possibility of fixing their diet;—no certainty of their continuing to attend, so that each case may be regularly followed up to its conclusion;—no possibility of making daily observations. When cases are severe, and the patients confined at home, there is not only the same uncertainty of strict attention to the injunctions respecting medicines and diet, but the student must lose a great deal of time in running from one house to another: and the physician or surgeon will not visit all such patients daily with his pupils; and, indeed, his pupils cannot accompany him in these visits, with any degree of regularity. In an hospital the patients are compelled to obey every injunction; and, being under the same roof, they may be seen at pleasure any hour of the day, without loss of time; so that long and repeated observation of their cases is easy.

When death occurs to a dispensary-patient, and an examination is permitted, the student loses still more time: for he must not only go to the house of the family, but prepare the body; and afterwards reinstate it; and, in all probability, will seldom be accompanied by the physician or surgeon. At hospitals the examination takes place without any loss of time; the student has nowhere to go; servants prepare, and sew up, and wash the body; and the physician or surgeon usually superintends the inspection. So superior are the advantages of hospitals, that, as I have already remarked, certificates of attendance upon them are required at all medical Universities, previously to examination for the doctorate; and although certificates of attendance at dispensaries are admitted by the Apothecaries' Company of London, and may be obtained at a cheaper rate than those of hospitals, the majority of English medical students voluntarily enter themselves to the medical practice of hospitals.

The inferiority of dispensaries is, indeed, acknowledged by their medical officers,

in the greater cheapness of their terms; and the Apothecaries' Company declare it, in their demand of a longer attendance at them than at hospitals. It is, therefore, much to be lamented that the Apothecaries' Company admit dispensary-attendance at all; since if, of the short period enjoyed by the medical pupil for the public study of his profession, a certain portion is necessarily devoted to the observation of cases, that portion should evidently be spent in witnessing them in what is acknowledged to be the most efficient manner; and if eighteen months can be spared for attendance on *dispensary*-practice, they can be spared for witnessing *hospital*-practice. Those who cannot see the necessity of hospital-attendance, for the purpose of observing, without loss of time, the most important diseases, their minute investigation, and accurate and unrestrained treatment by the physician,—cannot but admit the necessity of hospital-attendance for the purpose of witnessing the great accidents, and operations of surgery. The College of Surgeons receives no certificates of attendance upon the surgical practice of dispensaries. If, therefore, the student must attend an hospital for half his experience, it is indisputably best that he should acquire the other half within the same walls.

I will not scruple to add, that I think the student pays too much for hospital-attendance in London; that the entrance should not be to medical or surgical practice alone, but to the whole range of the hospital; and that the sum which is paid to witness the surgical practice only, would be a sufficient remuneration for the surgeons and physicians together; and I should rejoice to see the most meritorious among the senior students, rewarded gratuitously with the appointments of dressers to the surgeons, as well as of clinical assistants to the physicians.

Without an hospital, the professors who teach the practical part of the profession, not only are deprived of the means of properly instructing their pupils, but lose the great advantage of proving to them the truth of their statements, and the propriety of their precepts. One great source of my pleasure in teaching at St. Thomas's Hospital, was the opportunity of showing the pupils that I practised what I inculcated;—of rendering probable, or even proving to them, that what I advanced was true; and of referring from time to time, for illustrations of my descriptions, to cases which they had witnessed with me in the institution.

The last argument I will urge in favour of hospitals is, that they are also dispensaries. They have a dispensary-department, in which patients are attended to the same amount as at mere dispensaries. Besides all the inmates of St. Thomas's, the greater part of ten thousand out-patients are attended; and, although none are visited at home, this might readily be done without any farther trouble or expense, by the senior and best informed students; to whom such a trust would be an incalculable benefit.

*Large and Small Hospitals.*—For the greater part of these important objects, a small hospital would be sufficient;—a hundred medical, and a hundred surgical beds. This number of well-selected cases, assiduously studied, would answer all ordinary purposes, as well as the four hundred and fifty-eight beds of St. Thomas's;—one half of the cases in which are imperfectly, or not at all known, to the pupils. An hospital of this extent might, I am inclined to believe, be conducted at less expense than is generally imagined. An important advantage, however, is inseparable from a large hospital;—not that of affording a large number of examples of the same affections, but of giving a probability of the occurrence of the more rare;—nay, of the rarest diseases, accidents, and operations, during the period every student frequents it. Besides the opportunity of becoming fully acquainted with all the ordinary cases of Medicine and Surgery, it is indispensable to a full and perfect education, that instances of every disease and accident which he may afterwards have to treat, should be witnessed by the student.

The most elaborate description of a disease, or mechanical derangement, not only falls short of conveying an adequate idea, but the conception gradually fades away; or, if retained, is frequently not recalled when, after a lapse of time, the disease so described chances to occur, and probably we do not recognise it till another person names the nature of the affection; or, if we suspect its nature, we

still have our doubts. On the other hand, if diseases or accidents have once been seen,—“*oculis subjecta fidelibus*,”<sup>a</sup> when they again present themselves, they are immediately recognised.

A striking exemplification of these remarks came under my observation when a student. A poor man, labouring under true scurvy, applied to a surgeon on account of the horrid state of his mouth;—his gums being swollen, spongy, and bleeding; his teeth loose, and his breath offensive. The surgeon, not having seen a case of scurvy, supposed the disease of the gums arose from a bad state of the teeth; and extracted several in succession. He was then sent to another, of high eminence and enormous practice, who pronounced it a case of *fungus hæmatodes* of the gums; and admitted him into his hospital;—intending to resign him to his fate. Being visited, however, by a practitioner who had witnessed scurvy at a naval hospital, the nature of the disease was at once recognised; some lemon-juice, fresh meat, and vegetables were prescribed; and he was well in a week or two. The surgeons, who were not aware of the nature of the complaint, were well-informed men; and the disease was one which all have heard of, and the leading symptoms of which are universally known. But, though formerly very prevalent and fatal in London, it is now uncommon; and thus, from not having witnessed it, these two gentlemen committed a serious error. It is also of great importance to the student, that he should have witnessed all the rarer accidents and surgical operations; and for this purpose a large hospital is indispensable.

*General Education of Medical Men.*—While I rejoice in the establishment of an English School of Medicine in this city,<sup>b</sup> on a plan which, if well conducted, will render it equal to any, and far superior to most others, in the civilized world, I rejoice also that the School in question, forms part of a University. Nothing is more to be desired, than that those who go forth into the world to practise the healing art, should be men of excellent education. In most countries of the Continent this is the case. The great body of practitioners there, receive a general education at a University, previously to commencing the study of their profession. They in truth receive what ought to be the education of a physician; and they are physicians. In this country, those who carry on the great mass of practice,—those who, in addition to their original occupation of apothecary, have risen to the office, though not to the name, of physicians,—are indebted chiefly to their own exertions, for even their professional knowledge and skill. All the lectures, excepting perhaps those on Anatomy and Surgery, have been too scanty and superficial; and the clinical instruction has been conducted too generally in a most careless manner; so that clinical lectures were actually unknown in London a few years ago; and an extremely small number of those whose business in life was to practice medicine, ever thought of entering to the medical practice of an hospital, or even of a dispensary. No proper systematic method of practical instruction, whether medical or surgical,—no plan for intrusting the students with the charge of patients, is even yet established; and no better education is given by parents to those children intended for medical practitioners, than to those whom they destine for trade; and when the best part of general education should begin. The youth, with all his capabilities of literary and philosophical attainment, is hurried off to mix draughts and weigh powders, during the greater part of the day, for several years. The portion of time thus consumed, and the sum of money thus expended, would enable the youth of our profession to attain every acquirement of a high education. The young men who come to our schools, to prepare themselves for general practitioners, are, in the majority of instances, as gentlemanly in their sentiments and manners, as intelligent and anxious to learn every thing that their instructors are disposed to teach them, as are those sent to Oxford or Cambridge,—as are young men of whatever station in society, and in the previous enjoyment of whatever advantages. I trust that, ere long, the five years' apprenticeship to

<sup>a</sup> “Submitted to the faithful eyes.”—*Horace, on the Poetical Art; Line 181.*

<sup>b</sup> London.

learn the business of the dispenser will be abolished; and the youth will acquire a good classical education, a knowledge of the three great continental languages (French, German, and Italian), and no inconsiderable acquaintance with Mathematics, Physics, and Mental Philosophy. By a change of plan, and by practicable facilities, I am confident that all this may be accomplished with no great increase of expense; and the young practitioner be ready for the commencement of his active career, at the age of two or three-and-twenty; and no one will deny, that a given expenditure of money and of time, ought to be made to produce the greatest possible advantages. I hope that the Apothecaries' Company will, one day, rather require from those young gentlemen who go before them, testimonials of having received a respectable classical and mathematical education, and of being able to read the German, French and Italian writers in the originals, with the possession of a share of Physics and Mental Philosophy; than of having consumed five years, when the mind thirsts most ardently for knowledge, in drug-mixing, or such poor and desultory instruction as a private practitioner has time to bestow; and which must be as nothing before they begin, systematically and practically, to learn Anatomy, Physiology, and Chemistry, at a public school.

An eminent scientific professor at Utrecht, in a pamphlet published in English by Mr. Faraday, in answer to Mr. Babbage's complaint that science is on the decline among us, says:—"There are countries in Europe where no young man could think of studying medicine, Mathematics, or Natural Science, with the help of Latin only; and without being prepared, before entering the University, with a sufficient knowledge of German, English, and French. The ignorance of foreign science in England, cannot be attributed to want of zeal, but to a defect in English education,—the ignorance of foreign languages.

If it be alleged that an improvement in education, will make the general practitioner equal in knowledge to the physician,—“Then,” it may be answered, “so much the better.” I have no desire that the importance of physicians should be maintained by the depression of the general practitioner. If the physician is to continue as superior to the general practitioner as he formerly was, he must progress in the same proportion; he must not think of preventing the advance of the general practitioner; he must also step forward himself, to maintain his advantage. The physician who devotes himself to a limited sphere, and whose means allow him to appropriate more time than the general practitioner to his literary and scientific education, and to the subsequent study of his profession; and who—exempt, while in practice, from the toils of Midwifery, and the distractions which beset the ordinary practitioner—employs those advantages as his sense of duty may dictate,—he will thus acquire every reasonable ascendancy; and general practitioners will gladly avail themselves of his assistance, and recognise him as the supporter of the respectability of the profession. The mass of the middle classes of society, has begun a great movement in the acquisition of knowledge, in the discovery of rights, in the correction of absurdities, and in virtue and liberality of sentiment. The higher orders see the impossibility of arresting this progress; and titles and decorations will no longer command notice, unless supported by real excellence. Among the higher ranks there are some who, so far from viewing this upward movement with dread, step forward to promote it. So ought physicians to act towards the general practitioner;—to make every effort to improve his general education, and professional knowledge. In fact, all those who lecture or practise at public institutions, act (whether they will or not) contrary to the narrow views of interest; for they are occupied in imparting knowledge to the rising generation of general practitioners;—occupied in endeavouring to make them as learned as themselves.

In *me* such narrow views would be the height of baseness, and would be the height of ingratitude; for I hesitate not to avow,—I rejoice in this public opportunity of declaring, that to the general practitioners of England, Scotland, and Ireland, I am indebted for success in my profession. When I commenced my professional career, I determined upon seeking for success by working hard; and by conducting myself as well as the infirmity of human nature would allow. I determined, how-

ever long I might wait for success, never to fawn upon and run after my superiors, nor to stoop meanly to my inferiors; never to intrigue for an advantage, nor to employ trumpery artifices for making myself known to the public. For many years I toiled; and saw most of my contemporaries,—nay, of my juniors (who worked less, but were wiser in their generation) pass by me. I published work after work,—edition after edition; and paper after paper was honoured with a place in the Transactions of the first Medical Society in Europe.<sup>a</sup> I was physician to a large metropolitan hospital; and had attended there, and gratuitously out of doors, above twenty thousand patients. But in vain. In the year 1828 my profession was no more lucrative to me than in 1818, and was as short of my actual expenses. At that time the “Lancet” was pleased, now and then, to publish a clinical lecture, delivered by me at St. Thomas’s;<sup>b</sup> and my practice at once doubled. The following year it published the greater part as I delivered them;<sup>c</sup> and my practice doubled again. Next season,<sup>d</sup> the “Lancet” published them all; the “Medical Gazette”<sup>e</sup> followed its example; and my practice doubled a third time. This astonished me the more, as my clinical lectures were generally delivered with little or no premeditation; while all that I published myself had cost me great labour, many a headache, and much “midnight-oil.” It was through the general practitioners, in the large majority of instances, and through general practitioners (for the most part) with whom I had not the honour of any acquaintance, that the publication of those lectures accomplished my success. To the body of general practitioners, therefore, I owe a debt of gratitude. They have called me forth spontaneously, from no interested motive; and I cannot exert myself too much in the education of their successors.

*Books.*—Young men are generally frightened on hearing the almost countless names of medical authors; or on beholding the array of volumes in public professional libraries; and a melancholy, amounting even to despair, has seized many an upright and inquiring youthful mind. Should any one be suffering from this anxiety, let him take comfort from my sincere assurance, that very few of these volumes need ever be opened. The greater part are full of absurd hypotheses, narratives at present comparatively unimportant, and exploded practice. Many are little more than copies and compilations from others; and the real good that exists in them all, is to be found in the best modern treatises. Except authors and teachers, few can have a necessity, in the whole course of their lives, for poring over these ponderous tomes. Students, indeed, I am thoroughly persuaded, should never read any but elementary works; and their whole library cannot, with any propriety, amount to twenty volumes. One good work on Anatomy, one on Physiology, one on Chemistry, one on Botany, one on Materia Medica, one on Midwifery, one on the Practice of Medicine, one on Surgery, and one upon State-Medicine, should, in my opinion, constitute nearly the whole of a student’s library. The design of his education is to fill his head, not with opinions and strange facts, but with solid truth; and if, after three or four years’ close study, with the assistance of a regular attendance on lectures on all these subjects, and of unwearied observation in the wards and in the dissecting-room, he fully comprehends the contents of these few works, and deposits them in the storehouse of his memory, he will have done well, and will be prepared to practise his profession with honour.

## GENERAL PATHOLOGY.

---

*General Law of Mutability.*—It appears to be a law of the universe, that every thing shall undergo incessant change. Whether the universe be eternal or not;—whether we believe it has existed (according to the opinions of some ancient philosophers) from eternity, and is to exist to eternity; or whether we are so to understand Scripture, as that not only the arrangement of all things, but all things themselves, had a beginning, and must have an end,—however this may be, while the universe is in existence, it appears to be the law of the Creator that every thing in it shall undergo incessant change.

Both the animate and the inanimate world are in this predicament. The most minute aggregate of matter, and the largest material bodies, appear only destined for certain periods of continuation in their existing state. With respect to our own earth, we see that countries are continually lessened and destroyed by the encroachments of the sea and by eruptions; and, on the other hand, from similar circumstances, other countries are produced. It is probable, therefore, that the appearance of the earth at present, is totally different from what it once was, and that after a period it will be totally different from what it now is. Even with respect to other worlds, there is every reason for astronomers to believe, that many have been destroyed; and that some worlds which are now seen, are but fragments of others which have been broken to pieces.

*Period of Existence Limited.*—With respect to the animated part of the creation, every vegetable,—every animal, has but a limited period destined for its existence. This period varies exceedingly; for some animals are destined to live but a few hours, while others, again, appear to live for centuries.

But besides this definite period, every animated being is liable to be cut off long before its natural period arrives. Animals and vegetables are all exposed to violence of every description;—not only to *mechanical* violence, but to the destructive operation of a thousand causes; and to disturbance from the cessation of the circumstances which are necessary to their existence. One animal is destined to devour another while in its prime; nay, to destroy the element of what would be the young (the eggs, for example) of another; and myriads of insects are continually destroyed in storms. Constantly, therefore, the limit which Providence appears to have placed to every thing is curtailed. Every animal and vegetable is subject to be cut short long before that limit is reached; so that there appears to be a perpetual struggling throughout nature;—the Creator having, on the one hand, invested every animated being (whether vegetable or animal) with a power to exist for a certain time, and to resist injurious agencies; and having provided, on the other hand, injurious agencies without number, to injure and to cut it off before its time.

It has been said by some philosophers that, looking at man, one would suppose he was destined to live to all eternity;—that, at first sight, such a machine as the human body, unless destroyed by external violence, would appear capable of lasting for ever. And by experience alone we are taught the contrary. “*Primo statim aspectu, talis machina, nisi fortè causâ aliquâ externâ corrupta vel læsa, in omne ævum durabilis videtur. Et quidem solâ experientiâ contrarium docemur.*”<sup>a</sup> However, there is nothing in the appearance of the human machine which would lead us to suppose

<sup>a</sup> Gregory's “*Conspectus Medicinæ Theoreticæ.*” Book I; Paragraph 12.

that it could last for ever. Whatever we know of nature, can be learned only from experience; and it would be as correct to say, that because it is summer we should believe it will be summer for ever, or because it is day we should believe it will be day for ever, unless we have contrary experience, as it would be to say, that the human machine in itself appears capable of lasting for ever. We can learn nothing from taking a partial view of things; for it is impossible to form a judgment of nature, except by taking a continuous and enlarged view. It would also be contrary to all analogy, to suppose that the human machine is capable of lasting to eternity.

## SECTION I.—THE NATURE OF DISEASE.

*Positive Causes of Death.*—With respect to the injurious circumstances which are positive, and to which animals are exposed, and by which they may be cut off before their full period has arrived, they are those, in the first place, of mechanical violence; in the second, those of a specific nature.\* Many animals and many vegetables contain within them materials, which are destructive to the life of others.

*Negative Causes of Death.*—Animals are liable to be destroyed, also, from a want of suitable external circumstances; for a series of actions is incessantly going on in every animated machine, and those actions are maintained by external circumstances;—such as by a certain degree of temperature, by a certain surrounding atmosphere, and by a certain supply of matter to be taken into the mouth or stomach, or some equivalent organ. The deprivation of any of these may put a stop to existence, or impair it; and, on the other hand, the excess of some of them will have the same effect. The excess of food may destroy or injure life; and the excess of heat may cause serious injury, or absolutely consume the body. Besides this, the depraved quality of those external matters which are necessary to the continuance of life, will have an injurious effect. This is well illustrated by the effect of bad food.

*Temperature.*—One of the most common causes,—indeed, I may say, the most common cause of diseases, is a deviation with respect to external temperature. A certain degree of heat is required for the support of life; and a deviation in that particular is the most common cause of the diseases which we observe in this country. An excessive degree of heat produces one set of effects; an excessive degree of cold produces another; and an alternation of the two—from the body being suddenly exposed first to the one and then to the other (more especially if this exposure be partial)—is attended by the most serious effects. The greater number of diseases are inflammatory; and the most common cause of inflammation is sudden alternations, or other unfavourable circumstances, with regard to temperature.

*Air.*—Bad air is also a common cause of disease; but this does not arise from the want of oxygen in particular, as has been imagined; but from the presence of certain substances of deleterious quality. I believe it is found, that the quantity of oxygen in the air is the same in almost every country and in every situation; and it is the presence of other things, in addition to the oxygen, which produces the injurious effect. We see the effect of the bad quality of the air in unhealthy situations, where persons are *sallow* and *bloated*, and carry about with them marks of disease, visible enough to others who come from a healthy spot, although not allowed to exist by the parties themselves;—simply for this reason,—that, being so accustomed to what they witness, they conceive it to be their nature.

*Food and Labour.*—The ill effects of unwholesome food are seen every day. The body is rendered feeble; and when this takes place, whether from bad air or bad food, it becomes an easy prey to any other cause of disease which may present itself. Want of the rest necessary for the refreshment of the body, has also the effect of producing disease. Excessive action, too, either of the mind or any part of the body, has likewise the same tendency.

Thus, disease is continually produced from mechanical violence, from the presence of injurious agents, and from errors in regard to those agents which are abso-

lately necessary to the support of life;—whether the errors be those of excess, deprivation of proper quantity, or depreciation of quality.

*Hereditary Taint.*—This, however, is not all. When a disease has been induced, it frequently happens that a tendency to that disease is transmitted to the offspring of the sufferer; so that it requires no exposure of such offspring to the particular cause of the disease, in order to become its victim; but at a certain period of life, unless placed in very happy circumstances,—and perhaps in spite of the happiest circumstances possible,—the disease under which the parent laboured appears in the child, or in a still later offspring; and possibly cannot be controlled. Again: independently of the inherent disposition to disease, and the external circumstances to which the offspring is exposed, original malformation of certain parts of the body so disorders its functions, that sooner or later disease, which may end in death, makes its appearance.

*Derangement of Functions.*—When disease takes place, the functions of the body suffer disturbance. A series of actions is continually taking place in the body; and some of these, when “disease” (so called) occurs, become deranged. The circulation of the blood is altered; more is accumulated in some parts than there should be, and less in others. The temperature of the body is altered; it is too hot either partially or generally, or it is too cold. The feelings of the body are altered; they become too acute or too dull, or they become otherwise wrong. The strength of the body likewise is changed; in some few instances it is increased, but in the great majority it is impaired. What was done naturally in the body before this change took place, is now done either too little, or too much, or in a depraved manner. The products of the body are likewise altered. The sweat is not natural in its quality, any more than in its quantity; the urine, and the secretions poured forth from the intestines, become altered in quality; and I have no doubt that the excretion from the bronchial tubes, also, is changed in its constituent proportions. At last, not merely are the *actions* of the body, and the *products* excreted from it altered, but even the very *substance* of the body itself will become changed.

*Extent of Derangement.*—With respect, however, to all the changes I have just enumerated, they must evidently be in a certain intensity,—a certain degree of them must exist, for us to say that disease is present. A change, although (strictly speaking) a disease, may be so inconsiderable, that one would be laughed at for calling it by that name. A slight spot upon the surface,—a single point no larger than a flea-bite, no one would think of calling “a disease;” and yet, if there were a larger number of these, though the only difference consisted in amount (the nature and degree of each being exactly the same), we should not hesitate to say that disease was present. Therefore, when a deviation with respect to function or structure takes place, there must be a certain extent of it, or a certain intensity of it (one or the other), to justify us in saying it is really a disease. Logically and strictly speaking, disease is said to be “an aberration of function or structure of one or more organs from a sound state.” You will find this mentioned in some books, as the definition of a disease. But this is hardly sufficient; because, with respect to *structure*, and even with respect to *function*, a part may be sound, and yet be in a state of disease. A part may grow to a much greater size than natural,—there may be diseased bulk of the organ, although the structure is healthy. This is a rare occurrence; but sometimes it does take place. Generally, where there is increased bulk there is diseased structure; but it is possible for a part to be enormously large, without being altered in structure; and yet the person may be said to be labouring under disease. A person with an enormous liver, or brain, though no unhealthy change could be discovered in its texture, would nevertheless be pronounced to be in a state of disease. So with respect to the fluids; they also suffer very great changes, and yet there may be no fault of function. In the disease called “*anæmia*,”<sup>a</sup> where the blood is deficient in quantity, the disease may really be quite independent of any fault of the body itself. A mere want of nourishment may cause the

<sup>a</sup> From *an* (privative) *without*; and *aima*, *blood*.

blood to be of a diseased quality;—that is to say, not to contain its natural elements, but to be very watery,—to be thin and pale (the whole body becoming white or tallowy in appearance); and yet no function can be said to be diseased,—at least excepting through this want of nourishment. The body is ready to do all that is required of it, if proper food be given. This definition of disease, therefore, is more or less exceptionable. Besides: in a large number of diseases, the quality of the *fluids* is altered; and it is essential to a correct definition, that this should be taken into account.

With respect to the *extent* of affection which is necessary to exist in order to constitute a disease, there must be a great difference in various individuals; for the health of different persons is exceedingly various. What is health to one man, would be disease in another; just as the degree of strength which is natural to a delicate person, would be considered downright weakness in another. To obviate any difficulty of this kind, we sometimes find added to the definition of disease which I have already given,—“rendering assistance necessary.” The definition given in Dr. Gregory’s “*Conspectus*” is:—“A disease is present, when the customary actions of the body are either altogether impeded, or performed with difficulty and pain.” (“*Morbus adest, quum corpus tantum a statu sano deflexerit, ut solitæ actiones vel prorsus impediuntur, vel ægrè aut cum dolore perficiantur.*”<sup>a</sup>)

*Definition of Disease.*—Disease, therefore, may generally (perhaps) be defined to be,—“an aberration of function, or structure, or size, of one or more organs; or of the quality of the fluids, from the sound state; rendering assistance necessary.”

*Pathology, Definition of.*—This, however, it may be remarked, is only a definition of disease in general; I shall make some further remarks upon the definition of each particular disease hereafter. Diseases, therefore, are neither more nor less than alterations in the physiology or anatomy of the body;—in other words, morbid physiology, and morbid anatomy. This morbid state of physiognomy,<sup>b</sup> and this morbid state of anatomy,<sup>c</sup> are together called “Pathology.” The doctrine of diseases, whether as it regards function or composition, is called “pathology.”<sup>d</sup> There is an inclination, in the present day, to limit the word “*pathology*” to morbid anatomy. That, however, I think, is quite unjustifiable; for pathology is the doctrine of disease, whether it relates to function, or structure, or both. Pathology, therefore, is an unhealthy state (if I may so speak) of physiology and of anatomy;—the composition of the fluids, as well as function, being comprehended under the term “*physiology*”;—size, as well as structure, being comprehended under the term “*anatomy*.”

*Functional and Structural Diseases.*—Diseases are often divided into those which are “functional,” and those which are “structural;” but it is very common for the one to terminate in the other;—for diseases which are at first purely functional, to become at last structural. At any rate, many organic diseases do not at first exhibit themselves as such, but are ushered in by a change of function. It is possible that a minute change of structure may exist, long before it is discovered; and that minute change is enough to explain the alteration of function; but many diseases exist long, to all appearance, as mere functional disturbance, before they become structural. Many diseases remain functional,—at least they go through their course as a disturbance of function, never affecting the structure; but structural diseases almost always disturb function. It is evident that if the structure of an organ which is to perform a certain duty be much altered, that duty cannot be well discharged.

*Organic Diseases.*—Structural diseases are sometimes called “organic.” I believe that the words “*structural*” and “*organic*” are used synonymously, to express those diseases which consist in a change of composition and arrangement of the organ itself, and not a mere alteration in the mode in which it does its duty.

<sup>a</sup> Gregory’s “*Conspectus Medicinæ Theoreticæ*,” Chapter 1; Paragraph 24.

<sup>b</sup> From φύσις, *nature*; and λόγος, *a discourse*.

<sup>c</sup> From ἀνα, *about*; and τέμνω, *to cut*.

<sup>d</sup> From παθος, *a disease*; and λόγος, *a discourse*.

Perhaps the word "*organic*" is preferable to the word "*structural*;" and for this reason,—that some diseases of this description do not appear to consist in any alteration of structure, but merely in a diminution or an excess of bulk. Now in those cases (which, though they are rare, nevertheless do sometimes occur) where an organ wastes, or becomes larger than natural, and yet appears otherwise healthy, the affection cannot exactly be called "*structural*;"—the word "*organic*" better applies to them; and therefore, altogether, the term "*organic*" may be preferred to "*structural*."

*Disorders and Diseases.*—There has been an attempt by some to call the one set of complaints, supposed to be merely functional,—"*disorders*;" and the others, which are structural or organic,—"*diseases*." For instance: they call dyspepsia, or diabetes, a "*disorder*;" and ulceration or cancer of the stomach, or ulceration of the kidneys, a "*disease*." This plan, however, is not generally adopted. It might be very well if all persons agreed to adopt the terms in this sense. But that is not the case: indeed, so far from it, that, in most books, the expression "*organic* or *structural disease*" occurs; which would not be necessary if every one adopted the word "*disease*" to signify in itself a structural affection. Nay, so extensively is the word "*disease*" employed by some persons, that even accidents (as dislocations or fractures) are called "*disease*." You will find, in Cullen's "*Nosology*," that dislocation and fracture are arranged under the class of "*Local Diseases*."<sup>a</sup> The word "*disease*," then, is used by some nosologists very extensively. They employ it to signify accidents, mechanical affections, dislocations,<sup>b</sup> hernia,<sup>c</sup> and every thing of that description; and it is used by almost all writers to signify both functional and structural affections. I shall, therefore, use the word "*disease*" to signify, not organic affections exclusively, but all depraved conditions, whether functional or organic.

*Local and General Diseases.*—Disease may be considered according as it is *local* or *general*. Some diseases affect only one part, and others are supposed to affect the whole system. Fever, for example, was formerly supposed to be an affection of the *general system*, without the preponderance of disease in any individual organ. The labours of Louis, Cruveilhier, and Bright, however, have conclusively established the fact, that proper typhus, in every instance, presents a disease of the intestinal glands, more especially those of Peyer; while, with regard to fevers of a less malignant character, it is by no means proved whether they consist in a general disturbance only, or whether they depend upon a more local action for their cause. I can entertain no doubt, however, that there are such things as general diseases; and it appears to me that scurvy is of this description, for every fluid of the body seems vitiated;—at least the blood throughout the body is so, and all the solids appear to be in a similar state. There is no one part of the body that can be fixed upon as the seat of the malady. So with respect to ague. I cannot discover any reason for ascribing the disease to any one part of the frame; and I therefore think that it also is an instance of a general affection.

*Acute and Chronic Diseases.*—Diseases are also different from each other according as they are *acute*<sup>d</sup> or *chronic*.<sup>e</sup> Some diseases come on suddenly, last usually but for a short time, terminate either in health or death,—

—"Cita mors venit aut victoria læta,"<sup>f</sup>

<sup>a</sup> They constitute Orders 7 (Ectopiæ, from *εκτοπος*, *out of place*) and 8 (Dyalyses, from *διαλυσις*, to *dissolve*) of Class 4. A complete view and explanation of all the Classes, Orders, Genera, Species, and Varieties in Cullen's System, may be obtained at a glance, by means of a "Synopsis of Cullen's Nosology," published on a single sheet, by Butler, St. Thomas's Street, Southwark.

<sup>b</sup> From *δισ*, *out of*; and "*locus*," *a place*.

<sup>c</sup> From *εργος*, *a branch*;—alluding to its protrusion.

<sup>d</sup> From "*acu*," *to sharpen*.

<sup>e</sup> From *χρονος*, *time*.

<sup>f</sup> "A quick death or a happy victory arrives."—Horace's "*Satires*;" Book 1; *Satire* 1; Line 8.

and are called *acute*. Other diseases last for a long time—perhaps coming on slowly; but whether they come on slowly or suddenly, if they last for a long time, they are called *chronic*. Acute diseases, however, will sometimes, instead of terminating in health or death, become chronic;—that is, become less violent in degree, and go on for a length of time. Diseases, therefore, are to be considered acute or chronic according to their duration.

*Active and Passive Diseases.*—Diseases are also considered, by some, according as they are *active* or *passive*;—that is to say, according as they are attended with a degree of violence or excitement of the system, or no excitement at all. Some persons (indeed a large number) use the terms “*active*” and “*passive*,” and “*acute*” and “*chronic*,” synonymously; but this is an error which ought particularly to be guarded against. It does not follow because a disease is *acute*,—that is to say, exists for a short time, and then terminates,—that it is necessarily attended by violent symptoms; nor does it follow, because it lasts for a length of time, that these symptoms should not be active. This is illustrated, every day, in the case of rheumatism. It is daily spoken of as “*acute*” or “*chronic*,” and “*active*” or “*passive*,”—the term “*acute*” being used indifferently with “*active*,” and “*chronic*” with “*passive*.” In the chronic form of the affection, therefore, a person would not think at first of applying those remedies which, in an acute attack, would be beneficial;—taking it for granted that, as the disease is chronic, there is no violence; but that a slowness of mischief is going on, and that the remedies for the active acute state are improper. But we see, every day, cases of rheumatism which, although they have lasted for six or twelve months, or even longer, are still attended with all the symptoms of an acute disease;—that is, attended by heat of the parts, if not by quickness of pulse; and if blood be taken away, it appears buffed. It would, therefore, be a serious error to consider “*active*” and “*passive*,” as synonymous terms with “*acute*” and “*chronic*,” because, in acute diseases, the word “*acute*” refers simply to their short duration; and, in chronic diseases, the word “*chronic*” simply to their long duration; whereas the word “*active*” refers to the violent disturbance going on in the system or part, and the word “*passive*” to slow changes,—changes not of a violent description. A *chronic* disease may be *active*; and an *acute* affection may be *passive*. A person with an acute affection may lose all his powers, and the whole functions of the body may go on in the most languid way. Therefore “*acute*” and “*chronic*” are one kind of state, “*active*” and “*passive*” are another. An *acute* affection cannot be *chronic*, but it may be *passive*; and a *chronic* affection cannot be *acute*, but it may be *active*.

*Continued, Remittent, and Intermittent Diseases.*—Diseases differ, also, according to their uniformity of duration. Some continue with uniform tenor during their whole course,—without any very great deviation from the beginning to the end; these are called “*continued*.” Others, again, undergo a very great remission at regular periods, or at least pretty regular periods;—the symptoms not going off entirely till the disease ceases altogether, but undergoing such a relaxation of severity at such periods, as to acquire a character from this circumstance;—when they are called “*remittent*.” While others, again, will cease entirely from time to time (generally, too, at stated times), and recur again at certain intervals, so long as the person is affected with them; these are called “*intermittent*.” These varieties are particularly seen in the case of fever. Fever may hold a pretty uniform course;—never ceasing at all, or particularly diminishing, during the twenty-four hours, till its close; and then we call it “*continued* fever.” It may last for a day, a week, or several weeks. In other cases, there is a sudden diminution in the degree of heat, violence of pulse, thirst, and all the other symptoms, at a certain period in the twenty-four hours, and perhaps at longer intervals; but they do not cease entirely: such is the character of “*remittent* fever.” Others, again, cease entirely. The patient will be attacked at a certain hour, be ill a certain number of hours; and then recover perfectly, with the exception perhaps of languor: the disease then receives the name of “*intermittent* fever.”

*Continuent and Periodical Diseases.*—Many persons speak of “*continued*”

disease, as distinct from “remittent;” and it is so common that we are justified in using the distinction; but some make a nicer distinction, and use the word “*continued*” to include both “*continuent*” (which preserves the same tenor to the end), and “*remittent*” (which, although it never ceases, yet relaxes from time to time). If intermittent diseases recur and disappear at regular intervals, then they are called “periodical.” A periodical disease is necessarily intermittent; but an intermittent disease is not necessarily periodical. Intermittent embraces the circumstance of simple intermission, no matter when or how; but it embraces also regular intermission,—periodical disease. The presence of a disease which is intermittent, is called the “paroxysm,”<sup>a</sup> or “exacerbation”<sup>b</sup> (these being considered synonymous terms); and the interval which occurs between them, is called the “intermission;” or, in case of febrile disease, the period of apyrexia,<sup>c</sup>—the period of the absence of pyrexia.<sup>d</sup> I fear being troublesome in mentioning the meaning of so many terms; but it is absolutely necessary that they should be understood, before proceeding to treat of particular diseases.

Diseases differ, therefore, according as they affect function or structure; and as to whether they be local, or general; acute, or chronic; active, or passive; continued, remittent, or intermittent.

*Nature, Causes, and Seats of Diseases.*—Diseases likewise differ in their true inherent nature, independently of any other circumstances. They differ also as to their causes. Some are produced merely by an aberration as to some of the circumstances which are necessary to the support of life; such as the excess of temperature or food, or a deprivation of food or air, or a *diminution* of food or air. Others, again, are produced by *specific* causes,—by the agency of particular substances, the nature of which cannot be comprehended. Such, for example, is ague, which is produced only by a certain exhalation; and such is small-pox; and such are all those diseases which acknowledge a peculiar specific poison for their cause. Diseases differ likewise, according to the *organ* which they affect. There are some diseases which can affect almost every organ in the body. Inflammation is one which affects every part of the frame which has vessels; but there are certain diseases that can only affect particular organs. The tendency to produce gall-stones, can affect no other part than the biliary system. In addition, therefore, to all the circumstances previously mentioned, diseases differ as they affect any part of the body at large, or are necessarily confined in their operation to particular organs.

*Explanation of Terms.*—I must now enter a little more minutely into the explanation of certain expressions, which will be used frequently hereafter; otherwise I am in danger of being misunderstood. The whole doctrine of disease is called, collectively, “General Pathology.” Pathology is the science of disease,—“*ægroti hominis scientiæ*;<sup>e</sup>” while physiology is the science of health. General Pathology is commonly said to embrace four particulars:—1. General Nosology;<sup>f</sup> or, an account of diseases in general, and of their differences. 2. An account of the causes of disease; which is called “*ætiology*.”<sup>g</sup> 3. The symptoms of disease; which is called “*semeiology*,”<sup>h</sup> or, “*symptomatology*.”<sup>i</sup> 4. The treatment of disease; which is called “*therapæia*.”<sup>k</sup> There is, however, not only a *general* but a *special* pathology, which respects particular diseases; and if the epithet “*methodical*” be attached to “*nosology*,” an arrangement of diseases is meant;—a classification of the various affections to which we are liable.

<sup>a</sup> From *παροξυσμω*, to aggravate.

<sup>b</sup> From “*exacerbo*,” to be become violent.

<sup>c</sup> From *a. without*; and *πυρεξία*, fever.

<sup>d</sup> From *πυρ*, fire.

<sup>e</sup> “The science which relates to a sick man.”

<sup>f</sup> From *νόσος*, a disease; and *λόγος*, a discourse.

<sup>g</sup> From *αἰτία*, a cause; and *λόγος*, a discourse.

<sup>h</sup> From *σημεῖον*, a sign; and *λόγος*, a discourse.

<sup>i</sup> From *συμπτῶμα*, *συμπτωματος*, a symptom; and *λόγος*, a discourse.

<sup>k</sup> From *θεραπεύω*, to heal.

## SECTION II.—GENERAL NOSOLOGY.

I shall first speak of what is called "*general nosology*," or the consideration of diseases in general. These may be either *local* or *general*; but even when local, they seldom continue so without producing more or less general effects. Diseases vary in their symptoms, and in their course, according to the texture which they affect. The body consists of a certain number of textures;—the various parts of the frame may be resolved into a certain number of particular "*tissues*," as they are called. Now, some diseases affect certain textures; and others affect other textures; and the symptoms of diseases, and their course, are influenced very much by the texture which is thus affected. To take inflammation, for example: we shall find that the symptoms are very different when it affects a *serous* membrane, from what they are when it affects a *mucous* membrane. Again: the symptoms are very different when it affects the skin, or when it affects a bone. The symptoms of disease, too, and the course of diseases, vary exceedingly according to the organ. Diseases may not only attack a particular organ, but they may attack a particular texture in a particular organ, or they may attack all the textures of an organ. Now, when they attack any particular organ, the importance of that organ to the economy, the function which it performs in health, and the various relations of that organ, greatly influence the symptoms. For example: inflammation which may be of no consequence in the finger, may (though only to the same extent) be fatal when seated in the stomach; a little ulceration, of not the slightest importance on the hand, may produce death if it occur in the stomach; an affection in the brain, or in the heart, may be productive of very different results,—a very different degree of danger, from what it would if seated in many other parts.

*Increased and Diminished Action.*—Diseases vary exceedingly, likewise, in proportion as they are attended by *excessive* or *diminished* action. Some diseases are characterized by an inordinate, violent action of the part;—the natural state of the part seems augmented. Whatever is done in health, is done ten times more in disease;—at least for a time; till the strength is exhausted, or the state gradually subsides into health. Other diseases are characterized from the beginning, or nearly so, by a great diminution of action. The natural functions of the part decline exceedingly; so that depression is the character of the disease. If the affected part be, in ordinary circumstances, possessed of much sensibility, (the general surface, for example,) the progress of disease in it is characterized by a very acute sensation of pain. If the part be one the function of which is motion, the latter may become very intense; and convulsions may occur as the consequence. On the other hand, we may have a *diminution* of feeling,—perfect torpor,—insensibility; and such an absence of all power of motion, that the part is useless to the individual. Again: if the part be one which secretes, the secretion may be in *excess*; and if it cannot escape we have dropsy. The secretion, on the other hand, may be exceedingly *diminished*; so that, in the case of the kidneys, no urine can be formed; and, in the case of the skin, the surface shall be perfectly dry.

*Changes of Size and Consistence.*—Some diseases, among structural affections, are attended by a great dilatation of the part;—the part becoming much dilated, beyond its natural extent. On the other hand, in some diseases, the parts become contracted and diminished. In some diseases, the parts become exceedingly hardened; so that from being naturally soft, they become as firm as cartilage;<sup>a</sup> and are sometimes converted into absolute bone. Again: very firm parts will occasionally become perfectly soft; and bone will become as pliable as muscle.<sup>b</sup> I have seen the liver become softened down to a pulp, in the course (to all appearance) of three days. Again: diseased parts will become exceedingly full,—distended with fluid;

<sup>a</sup> From "*carnilago*;"—from "*caro, carnis*," *flesh*.

<sup>b</sup> From "*musculus*," the diminutive of "*mus*," *a mouse*;—from the resemblance to that animal when flayed.

and this may be either *general* or *local*. It may be either local congestion,<sup>a</sup> or universal plethora<sup>b</sup> of the body. In other instances, the parts become devoid of fluid, and shrink; and this is observed also generally or locally. Alterations of texture likewise take place, and alterations in the quality of the fluids. The texture,—to say nothing of induration, softening, hypertrophy, or atrophy,—the texture of the parts sometimes becomes perfectly different from what it is observed to be in the state of health. So with respect to the fluids, they will frequently be formed of a character totally dissimilar from what they should be. The urine is sometimes any thing but genuine urine; and the bile is sometimes so pale, that we can scarcely recognise it as bile; and so with respect to the blood itself; it is sometimes very little more than a reddish watery fluid.

*Hereditary, Congenital, and Acquired Diseases.*—The foregoing are important and essential differences in disease. There are, however, many other varieties, which are considered more or less *accidental*;—that is to say, which do not affect the nature and course of the disease. Some diseases are “hereditary,” for example; and this will not at all influence the nature of their course of duration; but some diseases may be hereditary in the particular individual; while other diseases are not hereditary;—not transmitted from parent or ancestor to offspring and posterity, but still are born in the individual. They seem to be implanted in him at his first formation; and then they are called only “connate”<sup>c</sup> or “congenital.”<sup>d</sup> A disease which is connate, or congenital, may be hereditary; but it is not necessarily so. All diseases which are neither hereditary, nor connate or congenital, are said to be “acquired.”

*Primary and Secondary Diseases.*—Then diseases,—to speak still of accidental varieties,—are sometimes “primary,” and sometimes “secondary.” Sometimes the disease which occurs is the first; but sometimes, after one disease has taken place, it is joined by another;—that is to say, it exists with another, or gives such a predisposition that another is produced; but it is of no consequence to the nature of a disease, whether it is primary or secondary.

*Sporadic, Endemic, and Epidemic Diseases.*—Again: diseases are sometimes said to be “sporadic,”<sup>e</sup> sometimes “endemic,”<sup>f</sup> sometimes “epidemic.”<sup>g</sup> A disease is said to be *sporadic*, when it occurs from an accidental circumstance occurring to any particular individual;—when it is a solitary accidental case. Hence, when a person, from exposure to cold, suffers inflammation of the lungs or intestines, he is said to labour under a sporadic disease. These are insulated cases, —having no connection with each other;—not having any general prevailing cause. But if diseases occur from some general and temporary cause affecting a whole population, then they are said to be *epidemic*. “Sporadic” and “epidemic,” therefore, stand contrasted with each other;—diseases of the former class being those which occur occasionally and accidentally, from some peculiar circumstance happening to the individual; while epidemic diseases are those which affect a large mass of persons, from some general prevailing cause. Again: diseases are sometimes said to be *endemic*;—that is to say, when they do not arise from any general influence at a particular time, pervading a population, but when they spring from certain causes fixed and inherent to a certain place;—when certain places in which people reside, send forth causes of disease, to which all persons who come to that spot are liable, but from which persons do not suffer unless they go there. This is the distinction between “endemic” and “epidemic” diseases;—the former being confined to the inhabitants of a particular spot; and the latter being those which arise from a general cause, taking place only from time to time, and pervading, not a particular spot, but a considerable population.

<sup>a</sup> From “congero,” to accumulate.

<sup>b</sup> From πληθω, to fill.

<sup>c</sup> From “con,” with; and “nascor,” to be born.

<sup>d</sup> From “con,” with; and “genitus,” born.

<sup>e</sup> From σπειρω, to sow.

<sup>f</sup> From εν, among; and δημος, the people.

<sup>g</sup> From επι, upon; and δημος, the people.

*Contagious and Non-Contagious Diseases.*—Another difference in diseases—not at all affecting their nature, their course or their treatment—is, that they may arise from a common cause, or from a specific contagion. Some diseases are contagious, and some are not; but the symptoms do not vary in their essential nature; so that we are continually very much in doubt, as to whether a certain disease is contagious or not. There is nothing in the disease itself, to make us say that it must necessarily be contagious: and the greatest disputes are carried on, as to whether a particular affection is or is not contagious.

*Period and Seat of Diseases.*—Diseases have likewise been distinguished according to the time of the year at which they occur; so that we have vernal, summer, autumnal, and winter affections;—*vernales, æstivi, autumnales, and hyemales*. Other accidental differences of disease arise from their seat;—whether internal or external; and then, again, as to whether they are fixed, or whether they wander. If they cease in one particular part, and appear in another, they are said to be “metastatic,”<sup>a</sup> or “retrograde,”<sup>b</sup> or “retrocedent.”<sup>c</sup> If disease suddenly cease in one part, and another become affected, a metastasis, or change of place, is said to have occurred.

*Severity of Diseases.*—Diseases differ according to their severity. Some are exceedingly severe, others are light;—some are said to be mild, and others are said to be malignant. Those which are said to be of a malignant character, however mild they may be in appearance, are sure to baffle all the resources of our art, unless we can eradicate the affected part by a surgical operation; which sometimes is, but sometimes is not, possible. The word “*malignant*,” however, is sometimes employed simply to denote a certain degree of severity;—it is a term of rather indefinite meaning. Small-pox is said sometimes to be “mild,” and sometimes “malignant;” and, again, a sore which is of a cancerous nature,—however trifling the pain attending at first, but which is sure to go on to ulceration, violent pain, and (at last) destruction of the part,—is also said to be “malignant.”

*Duration of Diseases.*—Diseases vary likewise as to their duration. If they be exceedingly short,—so as to terminate within four days,—they are called by Latin authors “*acutissimi*,” but if they terminate within seven days, then they are called “*peracuti*.” We have no English words to signify the difference between these two durations. If they terminate within fourteen days, they are called “acute;” if they run on to twenty days, then you will find authors calling them “sub-acute;” and some are so nice in their terms, that if they last forty days they call them “*acuti decidui*,” and all that run on above that period are called “chronic.” It is sufficient, perhaps, to remember, that an *acute* disease is considered to be one which terminates within *fourteen* days—a *sub-acute* one which terminates within *twenty*; if the disease extend to or above twenty days, we may consider it *chronic*;—at least, I fancy a *patient* would think we were justified in so denominating it.

### SECTION III.—ÆTIOLOGY.

*Classification of Causes.*—The *causes* of disease are generally divided by authors into two;—the “remote” and the “proximate.” The remote causes, again, are divided by systematic writers into two more;—“predisposing” and exciting.” The word “*cause*,” however, is in these cases used in a totally different sense. When we speak of “remote causes,” a very different idea presents itself, than when we speak of “proximate causes;”—in fact, the cause of the disease, properly speaking, can only be remote. The *remote* cause, for example, of fever may be bad food, and the depressing passions; and the exciting cause may be, according to some, a specific contagion. Now the remote causes of the first description are

<sup>a</sup> From *μεθίστημι*, to translate.

<sup>b</sup> From “retro,” backward; and “gradus,” a step.

<sup>c</sup> From “retrocedo,” to go back.

called “predisposing;” they render the body liable to become the prey of something, which has a tendency to excite the disease. The exciting cause of the disease might have had no effect, unless the body had been predisposed; and the predisposition might not have had the effect, unless the exciting cause had occurred. A circumstance, therefore, which inclines the body to become the subject of disease, is called, “a *predisposing cause*” (“*causa prædisponens*”); that which actually excites the disease, “an *exciting cause*” (*causa excitans*); and both together are called “*remote causes*” (*causæ remotæ*). They are called remote, I presume, because they are a little distance from the disease itself; and because the proximate cause is, to all intents and purposes, close to and all but the actual disease. In one sense, indeed, it is the disease itself.

*Proximate Cause.*—The application of this term (“proximate”) gives rise to a great deal of confusion to the student. He would imagine that disease could be nothing more than disease; and to call the disease “the proximate cause,” would be thought absurd; but the reason of this I will explain. In defining any particular disease, we are obliged to take into our definition only what we observe;—just as the naturalist defines any flower, or any mineralogical specimen, by merely taking what is the object of sense, and describing it with all the marks together; and thus we have what is called the “definition of a disease.” For example: in jaundice we take together the yellowness of the skin, the yellowness of the eyes, the yellowness of the nails, the whiteness of the fæces, and the high colour of the urine; and say that the patient certainly has jaundice. The jaundice is not the disease, strictly speaking; but the collection of symptoms under which the patient labours, is called “jaundice.” Thus the word “*disease*” is applied by nosologists, not to the single *cause* of all these symptoms, but to the *collection* of symptoms. Take epilepsy: a person falls down foaming at the mouth; struggling in every limb; perfectly unconscious; and afterwards, when he ceases to foam and struggle, he lies senseless;—such a person is said to labour under epilepsy. These particular symptoms, blended together, occurring in succession, are called “epilepsy.” Now in Cullen’s, and other methodical nosologies, the disease is defined according to mere symptoms;—all opinion,—all cause, is excluded. They take merely the symptoms, and call them the disease. It is perfectly right that it should be so. But these symptoms must have a cause;—there must be a cause for this disturbance in epilepsy;—there must be a cause for the bile going into the blood in jaundice, appearing in the urine, and not being able to find its way to the fæces.<sup>a</sup> The cause of the epilepsy, or of the jaundice, is the circumstance that produces all these effects; and that is considered to be the “proximate cause.” If the epilepsy arose from a piece of bone depressed upon the brain, we should say the proximate cause of the epilepsy was the spiculum of bone. If the bile were obstructed because a calculus was impacted in the hepatic<sup>b</sup> duct, we should say the impaction of the calculus was the proximate cause of the jaundice. The proximate cause, therefore, is in fact the disease itself;—the actual disease from which the symptoms arise. The *remote* causes are those that predispose to the disease, or actually excite it; the *proximate* cause is the circumstance to which the *predisposing* and *exciting* causes have given rise; and this circumstance, when present, produces all the external symptoms,—the visible changes.

But the word “*disease*,” when we come to any specific affection, is (in a nosological sense) applied merely to a set of symptoms;—to that which we can comprehend,—which is discernible; and, as nosologists, we should not apply the word “*disease*” to the cause of all these symptoms; but should call it the “*proximate cause*.” When speaking as *pathologists*, however, and not as *nosologists*, persons inquire,—“What is the actual disease in this epilepsy?—What is the actual disease in this jaundice? Is it an enlarged pancreas pressing upon the ducts? Is it a calculus sticking there? Is the disease a contraction of the sides of the ducts, or what is it?” But that is a different sense of the word “*disease*,” and it is necessary to

<sup>a</sup> From “*stercus, fæces*,” *dregs*.

<sup>b</sup> From *hπαξ, hπατος*, the liver.

state that the term is employed by methodical nosologists, and must be so by me, to signify a collection of symptoms; and not the true *cause*, which is at the bottom of those symptoms; for though we might be inclined to say that this was the real disease, yet it is not so considered, but has received the appellation—“*proximate cause*.”

I trust that the explanation now given, will hereafter prevent any confusion which might otherwise arise. From an imperfect understanding of this matter, persons quibble about what is, and what is not, disease. It is necessary to know that a set of symptoms, following in a certain order, or united in a certain collection, is called “a disease;” and the *immediate cause* of all these symptoms,—which some say is the real disease, is called by the best writers “the proximate cause.”<sup>a</sup>

*Occasional or Procatactic Causes.*—Exciting causes are, by some authors, called “occasional” or “procatactic.”<sup>b</sup> Generally, in England, we say “predisposing,” and “exciting;” but in foreign books a variety of other names are employed.

*Predisposing Causes.*—With regard to the *predisposing* causes of disease, they depend upon a very great number of circumstances. Each particular age, for example, is predisposed to particular affections. The child is predisposed to one kind of disease, the youth to another, the adult to another, and the old man to a very different set. Climate, also, causes a great difference in the disposition to disease; the season of the year, likewise, has a great effect; the habit of the individual, as to temperance and sobriety, and as to a natural or unnatural and artificial course of life, has a peculiar influence. All these circumstances cause a predisposition to different affections. In regard to some diseases, there is not so much a *predisposition* required, as a *want of indisposition*. Almost every one, for instance, will take the small-pox, the measles, and the hooping-cough: so that we can hardly say that there is a predisposition to these diseases. The cases in which they do not occur are rare exceptions; and we are more justified in saying, that the person is *indisposed* to them, when these diseases will not occur in spite of the presence of contagion, than that those who catch them are *predisposed* to them:—that is to say, by nature we are *all* more or less liable to them; and it would be almost an abuse of terms to say that we were *predisposed* to them. All that appears to be requisite is, that there should be *no indisposition* to them.

*Exciting Causes.*—With respect to the *exciting* causes of disease, they have been generally classed in three orders. 1. Those which excite or stimulate. 2. Those which depress or debilitate. 3. Those which exert a physical or physico-chemical action. Heat, and excess in wine, are *stimulating* causes of disease; the depressing passions, and an excessive loss of blood, may be instanced as *debilitating* causes of disease; and these debilitating causes are spoken of, by some Italian authors, as *contra-stimulating* causes. Many causes, however, cannot be said either to depress or stimulate solely; they exert a peculiar action, which is not to be thus explained. It is something we do not understand. For example: malaria,<sup>d</sup> which produces ague, is a certain agent perfectly unknown to us, except so far as regards the situation in which it is produced. Malaria produces a set of symptoms

<sup>a</sup> The proximate causes of disease consist in alterations either in the *structure* or in the *functions* of parts; and are therefore divided into *organic* and *functional*. The *organic* proximate causes may be divided into four classes:—1. Inflammation and Fever. 2. Depositions. 3. Gangrene. 4. Displacements. Depositions are of four kinds:—1. Natural Tissues in excess. 2. Preternatural Tissues. 3. Natural Fluids in excess. 4. Preternatural Fluids. Displacements are of seven kinds:—1. Intus-susception. 2. Hernia. 3. Prolapsus. 4. Extra-uterine Conception. 5. Miscarriage. 6. Fracture. 7. Dislocation. The *functional* proximate causes may be divided into three classes:—1. Spasms, and other examples of *increased* action. 2. Convulsions, and other examples of *irregular* action. 3. Palsies, and other examples of *diminished* action.—Dr. Fletcher.

<sup>b</sup> From προκαταρχη, to go before.

<sup>c</sup> In hot countries the skin and the liver are more liable to disease, and the lungs and the kidneys in cold; because these have, respectively, more to do in a hot and in a cold climate.—Dr. Fletcher.

<sup>d</sup> The Italian name of an intermittent, endemic in the Pontine marshes.

of so peculiar a nature, that we cannot say it is a mere depressive or contra-stimulating agent;—that is to say, though the first symptoms of ague produced by it are those of extreme debility, yet if we weaken the body to the same extent in various ways (as by bleeding and other means), we do not produce that train of symptoms known to us as intermittent fever. We have, then, “stimulating,” “depressing,” and “physical,” or “chemical” causes;—sometimes called “stimulantes,” “contra-stimulantes,” and “irritantes.” We must not, in medicine, be very nice about the etymology of our words,—that is to say, we must employ words of a certain meaning, so as to be clearly understood; but we shall find words signifying something very different from what their etymology would lead us to suppose. Nor is this remark confined to medicine; it applies equally to anatomy; and our only object should be to employ language intelligible among ourselves;—to know what ideas are meant to be conveyed, when certain expressions are used.<sup>a</sup>

An *exciting* cause may become a *predisposing*; and a *predisposing*, an *exciting*. For instance: malaria excites ague. But a person who has been exposed to malaria, may not have ague till he accidentally gets wet through; and then this *excites* the disease, to which the malaria had only *predisposed* him. Again: if a predisposition continue to increase, disease will happen without any exciting cause. Plethora of the head may increase till a fit of apoplexy occurs;—without stooping, overloading the stomach, or any common exciting causes.<sup>b</sup>

*Non-Naturals*.—Among the most common causes of disease, are aberrations with regard to six particular circumstances, which have been very strangely called “non-naturals.” The air we breathe, the food and drink which we take, the retentions and excretions, motion and rest, sleep and watching, and the various passions of the mind (which are all natural enough), are called by old writers “non-naturals;”<sup>c</sup> and others, seeing the strangeness of this expression, have called them “things necessary to life;”—that is to say, things which are necessary in order to the continuance of our existence. The great source of disease is,—an aberration of all these from that state which conduces to health. With respect to *air*, for example: vitiation produces a variety of diseases; such as fevers, and many others. Our health must depend much upon the wholesomeness of our *food* and *drink*, and upon a proper quantity of them. The body cannot bear more than a certain degree of *exertion*; many diseases, therefore, arise from fatigue. On the other hand, excessive rest and indolence produce a collection of fluids in various parts of the body,—stagnation, plethora, fatal dropsy, and various organic diseases. So with respect to *sleep* and *rest*, alternations are absolutely necessary; and we every day see persons who, for want of sleep, become the victims of fever, and gradually of the most destructive diseases. Again, with respect to the *passions of the mind*;—there is scarcely a disease (with the exception of those that depend upon contagion) to which they do not give rise; nor is there any one part of the body, in fact, exempted from disease through the passions of the mind. No one can imagine what a vast number of diseases, not only functional but organic, arise simply from unpleasant emotions of the mind;—that is to say, from grief and deep-rooted sorrow, from violent anger, from regret and chagrin, and all those feelings which are of an unpleasant character. On the other hand, it is also to be remembered, that emotions of the most agreeable kind,—excessive joy, for instance,—may have an effect almost as injurious as those which are of an opposite character.

*Air*.—With respect to the first of these non-naturals, the *air*, it may injure the

<sup>a</sup> This is a very *good* object, but it ought not to be the *only* object aimed at. The “expressions used” should, as nearly as possible, correspond with the “ideas meant to be conveyed.”

<sup>b</sup> “Predisposing” causes are always internal; “exciting” causes may be either internal or external. Sleep (which, in excess, produces disease) is an example of an internal exciting cause.—*Dr. Fletcher*.

<sup>c</sup> So called, because they do not enter into the composition of the body; but, at the same time, are necessary to its existence.

body by its weight or levity,—by the various electrical qualities which it may possess,—by its temperature, dryness, and moisture. Various winds produce, upon the human body, effects of the most curious kind;—according to the countries, or districts, or parts, over which they pass. With respect to temperature, it injures the body not only by its height or lowness, but also by its vicissitudes; and not only so, but according to its partial or general application to the body. A temperature that would do no harm if it were continued, would be productive of serious mischief if it suddenly succeeded an opposite temperature. A temperature which would do no harm if applied throughout the body, frequently does *great* harm if partially applied. Every body knows the danger of suddenly cooling, if the body be over-heated and fatigued; and of a draught applied to any one part of the body. Under this head, also, may be mentioned various effluvia and odours; as they are transmitted through the air.

*Food and Drink.*—Upon *food and drink*, another source of disease, I need say but very little; they may be injurious either by their quantity or quality.

*Retained Secretions;—Plethora.*—The great thing here alluded to by old authors, is the blood; and it was supposed formerly, that it might greatly injure the body mechanically by its excess, either absolute or relative: so that “plethora” formerly occupied a very prominent part among the causes of disease. Some curious distinctions are made by old authors on the subject of plethora. ‘They call it “absolute” or “true,” or “*ad vires*”<sup>a</sup> or “*ad vasa*,”<sup>b</sup> when the quantity of blood was absolutely in excess. They called it “apparens” when the blood was in its natural quantity, but expanded;—believing that it might be expanded by heat, and thus a temporary plethora be induced. When there was no actual increase of blood,—when the blood was not expanded improperly by heat, but the space in which it moved had become too small, this was called “*relative plethora*,” or “plethora *ad spatium*,”<sup>c</sup>—where the vessels, it was supposed, became contracted, and the blood was merely in excess, as compared with the contracted space. Plethora, however, may either be *general* or *local*. A local plethora is what, in modern language, is called an inflammation or congestion,—just as the case may be. When the blood is really in excess, I believe that it is generally of too rich a quality; that there is too little of its watery portion, and too much of the crassamentum.<sup>d</sup>

*Inanition.*—The opposite of plethora, is *inanition*. This is a state which is induced by excessive discharges, or from the want of food; so that the blood which was in the body is let out, or the blood which naturally escapes in the various excretions, is not replaced. Anæmia (bloodlessness; or, more properly, a watery state of the blood) will arise from a state of the system that is not at all understood; in which, although food is taken, nourishment is but very sparingly extracted from it. Cases of this description are seen continually: chlorosis is one of this kind. But the blood certainly is sometimes in fault with regard to its constituents; not merely as to whether it is too rich or too poor, but—as would appear by some experiments of a friend of mine (Dr. Stevens), and of Dr. Clanny—by the saline ingredients erring in quantity; so that the blood, in many cases of disease, is absolutely deficient in its saline particles.<sup>e</sup> It is evident, however, that diseases of the solids themselves will sometimes cause these aberrations of the blood; so that the blood itself is not the cause of the disease. It may become an instrument of farther disease; though disease of the solids originally gave rise to the aberration of the vital fluid.

*Undue Excretions.*—With respect, however, to the *excreta*, it may easily be conceived how excessive discharges occasion various diseases. The excessive discharge may consist of blood, of bile, of secretion from the alimentary canal (fæces),

<sup>a</sup> “Relatively to strength.”

<sup>b</sup> “Relatively to the vessels.”

<sup>c</sup> “Relatively to the space.”

<sup>d</sup> From “*crassus*,” *thick*.

<sup>e</sup> See “Observations on the Healthy and Diseased Properties of the Blood; by William Stevens, M. D.,” and “Hyperanthrax, or the Cholera of Sunderland; by William Reid Clanny, M. D.”

of urine, of perspiration, of saliva (seldom, however, doing much harm), or of semen. These are the fluids which particularly escape from the body, and the escape of which may do harm. But with regard to that last-mentioned (semen), although one must suppose that the excessive loss of the fluid must of itself be injurious, yet it is very certain that the *mode* in which that fluid is lost, exerts a very great influence upon the constitution.\*

*Exercise.*—With regard to *motion* and *rest*, I need not point out the ill effects of sluggishness on the one hand, or of fatigue on the other. Nor need I make any remarks with respect to *sleep* and *watching*; for they come under the same head as “motion” and “rest;”—sleep and watching being to the brain, what repose and motion are to the rest of the body.

*Mental Emotions.*—With respect to the *passions of the mind*, I mentioned that they are a frightful source of disease;—much more so than is commonly imagined. An immense number of cases of disease of the heart, and disease within the abdomen,<sup>a</sup> as well as of the brain itself, arise (I am certain) from unpleasant passions of the mind. It is not only *unpleasant* passions, however, that affect the body injuriously; violent emotions of the most *pleasurable* kind, will sometimes operate in the same way. History relates many accounts of persons who have died from excessive joy.

*Poisons.*—Besides those circumstances which I have just mentioned, the body is liable to injury from two very common sources; one of which is *poison* of various sorts;<sup>b</sup> which poison may enter the system by the surface, by the breath through the medium of the lungs, or by being swallowed. It is a very curious fact, however, that many poisons which act offensively when admitted into the body one way, have no effect when admitted in another; for it is an established fact, that the poison of hydrophobia, or of a serpent, may be swallowed with the most perfect impunity.

*Mechanical Injuries.*—In addition to poison, the body suffers much from *mechanical injuries*; which, of course, may affect almost any part of the body.<sup>c</sup>

*Predisposing Causes;—Age and Sex.*—Among the causes of disease which chiefly act by giving a *predisposition*, we may mention that of *age*. All periods of life are subject to their own diseases; whether we divide them with Shakspeare into seven,<sup>d</sup> or with those authors who mention five,<sup>e</sup> or those who mention more. We rarely see gout in an infant; nor is it common for old persons to have the symptoms of acute hydrocephalus. In short, every age seems marked out as particularly liable to be, if not destroyed, at least impaired, by particular diseases. The same is the case with respect to sex. Hysteria, which occurs only now and then in the male, occurs far more frequently in the female; and even when there is no reason to suppose an affection of the uterus. Of course, there are certain diseases which can affect but one sex.

*Temperaments.*—Disease depends much upon temperament.<sup>f</sup> We are all of some temperament, or some combination of temperaments; but excess of one tem-

\* From “*abdo.*” to *conceal*;—as the abdomen conceals the viscera within it.

<sup>b</sup> Dr. Christison divides poisons into three classes.—1. Irritant. 2. Narcotic. 3. Narcotico-Acid. Orfila has four.—1. Irritant. 2. Narcotic. 3. Narcotico-Acid. 4. Septic, or Putrefiant. Dr. Fletcher divides them into six classes:—1. Acid. 2. Corrosive. 3. Narcotic. 4. Narcotico-Acid. 5. Astringent. 6. Septic. The reader is referred to his “Physiological Classification of Poisons,” published as a Chart, by Butler, St. Thomas’s street, Southwark.

<sup>c</sup> The following are the principal causes which, either by their *presence*, by their *excess*, or by their *deficiency*, may excite disease:—1. Caloric. 2. Light. 3. Electricity. 4. Air. 5. Contagious and infectious Miasms. 6. Aliment. 7. Poisons, either swallowed or inoculated. 8. Pressure. 9. Blows. 10. Wounds. 11. Exercise. 12. Retained Secretions. 13. Sympathy. 14. Passions. 15. Sleep.—*Dr. Fletcher.*

<sup>d</sup> 1. The Infant. 2. The School-Boy. 3. The Lover. 4. The Soldier. 5. The Justice. 6. The Pantaloon. 7. Second Childhoodness. See “As you like it,” Act 2; Scene 7.

<sup>e</sup> 1. Infancy; from *birth* to *seven* years. 2. Boyhood; from *seven* to *sixteen*. 3. Adolescence; from *sixteen* to *twenty-five*. 4. Adult Age; from *twenty-five* to *fifty*. 5. Old Age; from *fifty* years to *death*.—*Dr. Fletcher.*

<sup>f</sup> From “*tempero*,” to *mix together*.

perament gives a great liability to disease. The usual divisions of temperaments are four:—1. Sanguineous. 2. Melancholic. 3. Phlegmatic. 4. Choleric. The *sanguineous* is marked by smoothness of skin, softness of hair, a quick pulse, a warm surface, great excitability of the whole frame, and generally a fair skin with florid complexion. The *melancholic*, on the other hand, is marked by a slow pulse, a dark swarthy complexion, dark and strong hair, and less susceptibility of emotion,—that is to say, of sudden violent emotion; although, when certain emotions take place, they are said to be more continued. The *phlegmatic* is marked by torpidity, paleness, and flabbiness. The *choleric* is characterized by reddish hair, and great excitability. However, these divisions, made by the ancients, are not so much attended to now. We often see these temperaments strongly marked; but they are also, at other times, variously combined.

An attempt has been made, within these few years, to divide temperaments differently; namely, according to the activity of particular parts. For instance: some persons have the chief activity in the head. They have a large intellectual development of the head, as some people say; and theirs would be called, perhaps, “the *cerebral* temperament.” Others, again, have a large broad chest, with a considerable development of all the muscles; and this is called “the *thoracic*, or *muscular* temperament.” Again: others are sluggish,—prone to eating and drinking, with protuberant abdomens; and are said to have “the *abdominal* temperament.” It is rather an abuse of terms to call these states “temperaments;” for I think the word “*temperament*” rather refers to a constitution and character of the frame altogether. Yet there is no doubt that these divisions occur; for you see some persons all intellect; others all muscle and chest; and some portly, with their large abdomens and lean pates;—their heads suffering in proportion to the predominant size of the abdomen. In truth, Dr. Thomas entitles his work,—“*Physiologie des Temperaments ou Constitutions.*”

Whether we call these conditions “temperaments” or not, it is well to know that these persons will suffer various diseases, according to the divisions under which they come;—as in the case of those who are of a sanguineous, phlegmatic, choleric, or melancholic temperament. They will be particularly liable to diseases of the *head*, if they be of the *cerebral* conformation; they will be subject to affections of the *chest*,—not of a phthisical, but of an inflammatory kind,—if they have a full *thorax*; and they will be subject to various *hepatic*, and other *abdominal* diseases, if the *abdomen* gain the sway. It is worth while to attend to this other division of temperaments; although, perhaps, the term itself may be objectionable.

*Peculiarities.*—Besides original temperament, acquired peculiarities take place by a long residence in a particular climate. By long residence in a particular spot, certain dispositions of the body are engendered; and a second nature, if I may so style it, is produced. The various occupations of life have the same effect;—the various trades have their various diseases. On this subject I cannot point out better works than Ramazini’s<sup>a</sup> and Thackrah’s.<sup>b</sup> Custom and habit—whether referable to trade or situation, or action, or any other circumstance—have also a very great effect in producing or preventing the cure of disease. For example: if a person who is in the habit of dram-drinking has a sore, nothing is more common than to observe, that in spite of the best surgical treatment, the healing process will not commence till the person is allowed his dram. After surgical operations, persons have been known to sink, through ignorance (on the part of the surgeon) of the general habits of the patient. Even death has occurred after operations, from the sudden abstraction of stimuli, to which the patient had been previously accustomed; whereas if he had been allowed his ordinary dram, the probability is that he would have recovered. This has been strikingly shown in other cases, where the knowledge was happily attained; and a good allowance of gin, after some severe accident, has caused every thing to go on well, though the patient at

<sup>a</sup> “Treatise on the Diseases of Artificers,” translated by Dr. James.

<sup>b</sup> “Effects of Arts, Trades and Professions, on Health and Longevity.

first appeared sinking. Bad habits are, therefore, sometimes to be *indulged*; although they should certainly never be *acquired*.

*Idiosyncrasies*.—Independently of what is called *temperament*, an individual may have a particular disposition, not acquired; it may be born with him, and be hereditary. A peculiarity is sometimes so exceedingly singular,—so totally different from what we observe in other people, that it is called *idiosyncrasy*.<sup>a</sup> It is nothing more than a peculiarity, either original or acquired by habit; and sometimes it is only congenital, while at other times it is hereditary. As an instance of this, we sometimes find a person who cannot eat a certain article of food. I recollect seeing a young woman who could eat the hardest salt beef, and digest it well; but if she took a raspberry, or current, or any other fruit, she was instantly thrown into the most violent spasms of the stomach; so that a stranger would have fancied her life in danger. These are called *idiosyncrasies*; and it is of great use to know them, because some persons are peculiarly affected by certain remedies; and that which is a proper remedy for the disease, may be improper for a particular patient.<sup>b</sup>

So much, therefore, with respect to the causes of disease in general (general *ætiology*). I will now proceed to consider the third branch of General Pathology;—the symptoms of disease in general (*semeiology* or *sympmatology*).

#### SECTION IV.—SEMEIOLOGY.

*Nature of Symptoms*.—*Symptoms* comprehend every thing which is observed in a patient out of the course of health;—"singulæ quæ in ægro præter naturam observantur res."<sup>c</sup> The most evident, and the most constant of these, are put together; and are said to constitute the disease. The disease is not the *cause* of the symptoms, but the aggregate of symptoms constitute the disease. I illustrated this with respect to jaundice and epilepsy;<sup>d</sup> the outward signs of which are jaundice and convulsions, while the inward state is the proximate cause.

*Essential and Accidental Symptoms*.—Symptoms may be "essential" (also called "pathognomonic"<sup>e</sup>), or they may be "accidental." The *essential* symptoms of disease, are those which are necessary to make the disease,—to constitute the idea of the disease. We cannot, for instance, suppose a patient to have pleurisy, unless there be a degree of feverishness, with sharp pain of the side, increased upon respiration, together with cough. These symptoms would be called "the essential symptoms of the disease;" yet no one of them would make the disease. A patient may have feverishness without pleurisy; or a sharp pain (either muscular or neuralgic) in his side without pleurisy; or, again, he may have cough without pleurisy. These symptoms, then, are altogether essential to the disease; but no one of them constitutes it. If, however, a symptom be so important to the disease that the latter cannot be present without it, then it is called "pathognomonic;"—a symptom without which we could have no conception of the existence of the disease. There are, however, but few of these symptoms. In jaundice, the yellowness of the skin, of the sclerotica,<sup>f</sup> and of the nails, is pathognomonic. Without making any farther inquiry, we may be sure that the patient labours under jaundice; but, in general, we make out the disease from the groups of essential symptoms, and from taking into consideration every circumstance of the case. Besides these symptoms, others are *accidental*. Many cases have symptoms

<sup>a</sup> From *idios*, peculiar; *syn*, with; and *krasis*, a temperament.

<sup>b</sup> The principal circumstances which predispose to disease, may be summed up under the following heads:—1. Age. 2. Sex. 3. Temperament. 4. Idiosyncrasy. 5. Habit of Body. 6. Climate. 7. Situation. 8. Season. 9. Diet. 10. Trade or Profession.

<sup>c</sup> Gregory's "Conspiculus Medicinæ Theoreticæ." Chapter I; Paragraph 26.

<sup>d</sup> See Page 43.

<sup>e</sup> From *παθος*, a disease; and *γινωσκω*, to know.

<sup>f</sup> From *σκληρυνω*, to harden.

which are not at all necessary to the disease, since it has frequently existed without them.

*Positive and Negative Symptoms.*—You will find symptoms also spoken of as “positive” and “negative;” and it is of great use to attend to the latter. “A negative symptom” is, perhaps, an improper expression; as, properly speaking, a symptom must be positive. But, from the *absence* of certain circumstances (or symptoms) we frequently make out the nature of a disease. If there be two diseases with certain symptoms common to both, but one of them has a symptom which the other never has, then, if that symptom be absent, it enables you to make out the true nature of the case. Hence the absence of certain symptoms is frequently of as great importance to be attended to, as the presence of others.

*Diagnosis of Diseases.*—From the presence of the symptoms chiefly, but not entirely, we make out the character of the disease; and the determination of the character, the name and nature of the disease, is called the “diagnosis.”<sup>a</sup> To speak again of jaundice:<sup>b</sup> from the yellowness of the skin, the whiteness of the fæces, and dark colour of the urine, we make our diagnosis, and say the disease is jaundice; although, indeed, we may do so merely from the yellowness of the skin and of the sclerotica. But, frequently, the diagnosis is not easily made out from the symptoms alone. It is necessary to look into the exciting and predisposing causes of the disease, to ascertain what predisposition the patient is likely to have; also to ascertain to what exciting cause he has been exposed; and then—conceiving what it is likely would ensue, and observing (as far as possible) what actually has ensued—we are enabled to form a much better conclusion as to the real character of the affection. The diagnosis is also materially assisted by attending to the history of the case;—not merely observing the symptoms that present themselves to our notice, but inquiring carefully of the patient the whole story from the beginning. We thus ascertain whether these circumstances confirm what we suppose to be the nature of the case. In making out the character of the disease, it is also of great importance to learn the effects of any previous treatment that may have been adopted. If vigorous treatment has been employed, and has produced no effect whatever, there will be great reason to doubt the propriety of the view which has been taken, with respect to the nature of the affection. In making a diagnosis, all these points are to be scrupulously attended to.

It is in making an accurate, careful diagnosis, that the medical practitioner chiefly shines. When the nature of a disease is once ascertained, it is no difficult matter to treat it. Other qualities of mind are then required;—frequently only courage, or mere perseverance; but it is in making a diagnosis,—in ascertaining the character of a disease, that the scientific practitioner outshines the inferior. Unfortunately this is a point not attended to as it ought to be. Many persons pride themselves in being good practitioners; because, without knowing what is the matter, they can say what will do good. It is an unscientific way of proceeding; and, even if I could not practise better for making a good diagnosis, still I would be as particular on that point as possible, for the sake of observing a good general rule,—for the sake of endeavouring to treat the patient better than I otherwise could, notwithstanding all my conceit; and for the purpose of being ready to meet any unexpected emergency that might arise. A medical man who will not take the trouble to establish a diagnosis, is just like a surgeon who will not condescend to learn the anatomy of hernia; but who says that he knows if he cuts this way and that way, he shall liberate the entangled parts, and accomplish the operation as well as the best. I have witnessed this; but, then, what are such men when a difficulty arises? They are lost in perplexity, and glad to apply to those who know better. It is impossible to be too minute in making a diagnosis.

Not only is it necessary to make a diagnosis as to the general character of the disease, but also to ascertain what variety of the affection it is (whether it is one with strength or weakness); and to weigh the minutest circumstances respecting

<sup>a</sup> From διαγνωσκω, to distinguish.

<sup>b</sup> See Pages 43 and 49.

the case. This is, perhaps, an exercise of patience; but it is a highly gratifying exercise, especially when it is found that a correct diagnosis has been made.

*Prognosis of Diseases.*—The judgment formed as to what will happen in a case, is called "*prognosis*."<sup>a</sup> It is quite essential to the formation of a correct prognosis, that an accurate diagnosis should have been previously made; for if the nature of the affection be not known, it is difficult to pronounce an opinion as to the probable termination. For the sake of making a prognosis, all the symptoms must be observed, and the history of the case learned,—exactly as in making a diagnosis; but there is something more than that to be done. The direct tendency of the disease ought to be known;—the course which the disease is always inclined to run; and the course which it is likely to run in the particular individual, according to age,—sex,—previous habits,—and all those circumstances which I have previously mentioned, as to individual peculiarities;<sup>b</sup> and in proportion as it is in our power to put into practice requisite curative means. There are some cases in which, if we were allowed to practise our art freely, we should make a favourable prognosis; but in which, our hands being tied,—as they are when others, ill informed or inactive, are called in over us,—we must give an unfavourable prognosis;—simply because the patient must be allowed to die. In making a *prognosis*, there is frequently less skill required than in establishing a *diagnosis*; for some persons, with a sort of tact, will tell whether an individual is in danger or not, without knowing what is the matter with him. Many persons who have no knowledge of medicine, or at least very little, have such strong perceptions, that—from the aspect of an individual, and from general observations of their own—they are enabled to give a very correct prognosis, either favourable or unfavourable. This I know to be the case. There are a great many intelligent officers, who—from seeing their men fall around them in battle, and sick in hospitals—have become, in one sense of the term, good doctors; and though they are not able to cure the disease, or tell what is the matter, they will be able to give a shrewd and correct guess as to how matters will turn out. But although some people, by nature, are well qualified for this, while others are not, yet the medical man must be taken as he is; and whether he does or does not possess sufficient natural sagacity to make an accurate *prognosis*, it is his duty to make as careful a *diagnosis* as he can;—in order that he may make as good a prognosis as possible. If his intellect be not of an acute description, yet, by knowing the case, and by the aid of science and minute observation, he will be able to form as good an opinion, as the man who, by nature, is qualified for these things; and if with science and observation be combined native sagacity, then I need not say, that his prognosis will be much superior to that of that of the individual who trusts alone to his natural powers.

Such, therefore, is what is meant by *diagnosis*, and *prognosis*; and I cannot too strongly recommend the most careful attention in establishing the former. Whether the patient can be cured, or not, it should be a solemn rule to investigate the case to the utmost. It is only by this plan we can profit ourselves, or that those who come after us can profit. If we be not careful, we cannot advance science; and the next generation will be none the better for us.

*Diathesis.*—There is a term which I have not yet explained, or even mentioned;—namely, the word "*diathesis*."<sup>c</sup> When the body is particularly predisposed to any kind of affection, it is said by some to have that particular *diathesis*, or a disposition to it. The term, however, is generally limited to two states;—an inflammatory state; and a state of weakness, or debility, if not of putrescency. One is called the "*phlogistic*," or "*sthenic*" (which means "*strong*"); and the other the "*asthenic*," or "*weak*." When, for instance, a person labouring under any particular complaint, is in a high state of excitement, with a full and strong pulse, and increased heat of body, he is said to have the *sthenic*<sup>d</sup> or *phlogistic*<sup>e</sup> diathesis:—in

<sup>a</sup> From *πρὸ*, before; and *γινώσκω*, to know.

<sup>b</sup> See Pages 48 and 49.

<sup>c</sup> From *διατίθημι*, to dispose.

<sup>d</sup> From *σθένος*, strength.

<sup>e</sup> From *φλογίζω*, to burn.

fact, an active inflammatory state of the body. If, however, the state be one of debility (so that any disease which is actually present is attended with weakness), and still more if there be extreme collapse, and a disposition to putrescence, then it is called the *asthenic*<sup>a</sup> diathesis. I believe, in modern times, these terms are rarely used, except when a certain disease is present; so that they really imply, not the disposition to disease, but the character of the disease;—as to whether it is actively inflammatory (attended by strength), or whether it is attended by weakness. In this country, we seldom hear persons use either of these terms, except “phlogistic.”

The word “*diatheses*” is used by old authors in other senses;—to signify, for instance, the general disposition to disease at any particular season; so that the constitution of the period was said to be its diathesis. If the disposition of any particular season of the year,—not the regular seasons,—were to produce such and such kinds of disease, the word “*diathesis*” was applied to that disposition;—to the disposition, if I may so speak, of the atmosphere at the time. But, generally speaking, the word is used as I have pointed out above. However, sometimes a constitutional disposition to certain diseases, when present, is called a diathesis. For instance: it is not uncommon, in practice, to hear persons talk of a “scrofulous diathesis.” Where a person has every look of scrofula, with its actual presence in one part, individuals say,—“That is a scrofulous diathesis.” A disposition to many other kinds of disease, when present, is sometimes called a diathesis; but it is the *phlogistic* diathesis of which mention is most frequently made. This term is sometimes used to signify that full state of the body, which would render a person very liable to an active inflammatory affection; but is certainly more frequently limited to that state, when the disease has actually begun. Now and then, persons with merely a full pulse, are said to be labouring under the phlogistic diathesis; but that state is characterized more particularly by the word “*plethora*,” of which I lately spoke.<sup>b</sup>

Let us now consider those symptoms of disease, on which the diagnosis and prognosis are in a great measure to be founded. The symptoms of disease may be divided, perhaps, in one point of view, into two kinds:—those which are discoverable by the patient only; and those which are discoverable by the by-standers also, or by them alone.

*Uneasy Sensations.*—There are some symptoms which a patient alone can ascertain;—for example, his feelings. He it is that feels the pain, and it is a lucky circumstance that it is so; for if the doctor felt the pain as well as the patient, there are but few who could stand the practising of the profession. We know little about the pain, except from the patient's account; and in many cases, in public practice, we are deceived. We have, however, only done our duty in listening to the patient's description.

*Pain.*—With respect to *pain*, it is of various kinds:—it may be “sharp,”—“stabbing,”—“darting,”—“shooting,”—“lancinating.” These are all words used by patients. At other times the pain is not of this character, but dull; and then we call it an “ache;” and sometimes patients add the word “*pain*,”—making it “aching pain.” Sometimes pain is described as “throbbing” and “pulsating;” and patients also complain of “pricking” pain,—as though a number of needles were being pressed into them. These things are all of great importance to be attended to, because they frequently show the seat of the affection; and according as a patient describes his pain to be sharp or dull, throbbing or pricking, so we frequently ascertain whether he is telling the truth or not; because the probability is, that it will be of a particular character; and we may ascertain whether his account agrees with what we should, *a priori*, expect him to describe. We sometimes hear pain spoken of as “smarting;” and, in some affections of the abdomen, a patient complains of “broiling” pain. It appears to be a high degree of smarting, with a sense of burning.

If pain be increased by pressure, or by the application of stimulants, then we

<sup>a</sup> From *α*, *without*; and *σθενος*, *strength*.

<sup>b</sup> See Page 46.

say there is "tenderness;" but perhaps the word "*tenderness*" is more properly restricted to pain increased upon mechanical pressure. There are other feelings continually described by patients; as, for instance, a feeling of "dead weight." This is particularly the case with respect to the head. We sometimes hear persons complain of "fulness,"—as if a part were excessively full; and now and then this sensation rises to such a pitch, that the part feels as if it would burst; and then we call it a feeling of "tension." A feeling of *tension*, appears to be a high degree of a feeling of *fulness*. Now and then, patients complain of a sensation of "pins and needles;" which is very different from the sensation of pricking pain,—as if needles were being run in; it is as if the pins and needles were rather blunt. It merely gives the lowest sensation of this kind,—not amounting to pain. "Pricking" pain is of a very different character;—for instance, that which people frequently complain of from inflammation of the urethra, in gonorrhœa. They experience a pricking pain along the urethra. But the sensation experienced when the hands and feet are "asleep," is not called *pain*,—patients say they feel as if pins and needles were there. You will frequently hear persons declare, that they have an indescribable uneasiness in a part,—a sensation which nearly drives them mad; but they will not allow it to be *pain*. I have known this sensation occur in different parts of the body. I recollect one lady who had it in the neck; so that she was obliged to walk about the room, followed by a servant rubbing her neck, night and day. Unless this was done, the sensation nearly deprived her of her senses; and her countenance betrayed the greatest distress. You will find other sensations spoken of by patients;—a "creeping," a "crawling," or a feeling as if water were trickling down them. There are also symptoms which approach nearly to pain,—"*itching*" and "*tingling*;" which may be almost insupportable. Tinging is a high degree, I imagine, of what is called "*itching*," united with a sense of "*pricking*." With regard to other sensations, there is nausea felt in one part,—the stomach; and now and then persons have an excessive sensibility of one particular sense,—of the eye or the ear, for instance.

*Exhaustion and Debility.*—Besides these symptoms, people have a feeling of great exhaustion, or debility; and this is a point strictly to be attended to, in forming the prognosis in an acute disease; for sometimes it is a fatal symptom. When a patient, for example, after inflammation of the bowels, has no pain, but a feeble pulse; and complains that he is so weak, that he feels as if he should die,—that he never felt such weakness in his life, we may be almost sure he will be dead before the next day. On the other hand, this feeling is very deceptive. Women are subject to a sinking sensation at the epigastrium. They tell us they feel as if they had no inside; and are sure they are about to die; but the feeling is quite delusive. In the former case, after an acute disease, from seeing all, or the greater part of the symptoms decline, we might judge that the patient would soon get well, and that this feeling of weakness was nothing more than might be expected after severe indisposition; but we must take into account other symptoms,—particularly the weakness of the pulse. But with respect to these females, we find the pulse good; and they are able to walk about, notwithstanding all the depressive feelings of which they complain. This is a very remarkable circumstance; and I shall find it necessary to draw attention to it, when speaking of diseases of the stomach, and of hysterical affections.

*Drowsiness, &c.*—Patients, also, can alone be conscious of drowsiness, *deficient* appetite, *inordinate* appetite, and *depraved* appetite: although, with respect to many of these things, we can often, by other circumstances, ascertain whether they are telling the truth or not. It is to the patient, likewise, that we must trust for the existence of tenesmus<sup>a</sup> and of strangury;<sup>b</sup>—a frequent desire to go to stool, and a painful and frequent desire to make water.

There are some symptoms, too, which are derived from other senses than those

<sup>a</sup> From *τείνω*, to constrict.

<sup>b</sup> From *στραγγέ*, *στραγγος*, a drop; and *ουρον*, urine.

of general feelings; and these are referable to the *ear*. Patients will continually complain of the most violent "beating pulsation" in their head; and frequently, too, of a "snapping" and "cracking" there. Such symptoms undoubtedly do exist, but we can take no cognizance of them. With respect to *sight*, we must depend on the patient's account for the occurrence of flashes of light before the eyes; and for the symptom so common in many diseases,—moats floating before the eyes; and for double vision, or diplopia;<sup>a</sup> and likewise for the symptoms of giddiness or vertigo.<sup>b</sup> On the patient, also, we must depend for symptoms with regard to *taste*. Some have in their mouth a bitter nauseous taste, of which we cannot judge. So with respect to *smell*;—now and then persons experience a most disagreeable odour, which no other person can notice. There was a case of hydrophobia at Guy's Hospital, in which there was an instance of an accidental symptom, and that a symptom to be ascertained only by the patient;—the patient experienced a most disgusting odour. This occasionally happens in cases of insanity. Now and then the smell which the patient perceives, may be noticed by other persons; because it arises from some disease within the nose. There are still other symptoms, of which the patient alone can give an account; such as defects in the senses;—a loss of sight, of taste, or of hearing. So with respect to many mental circumstances; such as the loss of many desires, and a feeling of strong desires;—for all these we must rely much upon the patient.

All these are symptoms which the patient alone can know any thing about. We all know something about them, because we are more or less ill at some part of our lives; but the medical attendant must take the patient's word for these sensations;—at least he cannot ascertain the existence of them directly. He can only ascertain, by other symptoms, whether the patient is probably telling the truth.

*Altered Appearances.*—I shall now proceed to consider those symptoms which are perceptible to the practitioner also, or to him only. In some writers, "symptoms" and "signs" are distinguished from each other; but I think it mere trifling to dwell upon such matters. With respect to those symptoms, however, which others observe, of course the patient, for the most part, may observe them likewise.

In observing the symptoms of disease, it is right to remember that Providence has blessed us with five senses; and all these five senses it would be ungrateful, as well as unscientific, not to employ. I am led to speak in this way, on account of its being a modern practice to employ the ear extensively. Those who do so were formerly laughed at as innovators;—as people who took unnecessary pains, and were perhaps attempting a piece of quackery, in order to produce an impression on their patients. If nature has blessed us with hearing to observe certain phenomena around us, there can be no reason for not employing it, when we come to observe the phenomena of disease; and if it be a fact, that there are symptoms of the most useful nature cognizable by the ear only, it is our duty to employ our ears for the purpose of detecting them. We are bound, I think, to employ all our five senses in the investigation of disease. The senses, however, of which we chiefly make use, are those of sight, hearing, and touch; but the smell, and in some instances even the taste, may be called in to our aid;—the smell, however, much more frequently than the taste. It would be as absurd to shut our ears, as to shut our eyes; yet, because the extensive employment of hearing has only been introduced lately, those who were not instructed in this point when they were students, are, some of them, too proud to learn in their old age; and are good enough to pity us younger men.

As to those symptoms which are cognizable by our various senses, they discover themselves in every part of the body, from the head to the foot; but the two parts which give the chief symptoms to the sight, and (I may say) to the touch, and the chief symptoms not only in reference to themselves but to all other parts of the body, are the *head* and the *hand*. It has become the custom, in all civilized nations, to cover all parts of the body except the face and hands; and these two parts afford

<sup>a</sup> From *διπλοος*, double; and *ὀπτομαι*, to see.

<sup>b</sup> From *verto*, to turn.

far more information than any others, respecting the state of the body, and respecting diseases that are present, and not seated in these individual parts, but at a distance. It is certainly a striking coincidence; but we must remember, that while necessity compels mankind to keep the face, and almost always the hand, uncovered, Providence has ordained that these same two parts shall convey the chief information to others, respecting our mind and body.

With respect to the face, we observe that it gives us two sorts of information;—first, as a mere portion of the body only,—a portion of the surface which is far more affected by every change than any other, excepting the hand, and therefore so far as it is *face*; and, secondly, it gives us another description of information so far as it is *countenance*,—so far as it expresses the state of the mind, and the state of the feeling altogether. The observations which we make upon this part of the body, then, may be considered as they respect simply *face*, and as they respect simply *countenance*.

*Alterations in the face.*—With regard to the face, as really a part of the surface of the body, if there be fulness of blood, it is shown particularly there. If we were to take the same quantity of surface in any other part of the body,—the abdomen, back, or thighs, for instance,—we should not get the same information from the part, simply as surface, as we do from the face. If the body be at all full, we see it in the face. If the circulation be rapid, and the heat considerable, it is the face that shows it; for the cheeks become tinged much sooner than any other part. If there be the least degree of coldness, we perceive it in the cheeks, nose, and lips. We discover hectic fever in an instant, by the red patch upon the cheek. If the patient be labouring under difficulty of breathing, we find the eyes immediately suffused, the lips more or less livid, and the whole face frequently of a leaden hue;—sometimes, indeed, I have seen it black. If it be jaundice that the patient labours under, we instantly discover it in the face. By one part of the face (the eye) we can detect it, long before it appears in any other part of the body, except the hand; and when the disease has nearly declined, it is in the face as well as in the hand, that it lingers the longest. In the white of the eye we perceive the presence of jaundice, before it is apparent anywhere else, except at the root of the nails. If the patient be bloodless, it is first discovered in the paleness of the face, the want of the usual vermilion of the lips, and the absolute paleness of the tongue. There is not a white crust upon the tongue; but it is absolutely blanched. Two of the chief marks of scrofula are shown in the face;—the dilated pupil, and the tumid under lip.

From the face *altogether*, simply as a part of the body, we are able frequently to tell at once that the lungs are affected, or that there is a great disposition to affection of the lungs. It is sometimes impossible to doubt for a moment that, if the patient be not labouring under phthisis, it will soon approach. From the peculiar appearance of the countenance, particularly from the appearance of the eye (its transparency), together with the languor of the cheeks, or the flush upon them,—no doubt can exist as to the nature of the disposition. And with respect to other parts, we can tell that the patient is labouring under organic disease of the abdomen, from the look of the cheeks. I do not say it is so always; but the appearance of the face is of great use, in enabling us to detect that condition.

In organic diseases of the stomach, intestines, and surrounding parts, there is often a faint greenish yellow appearance of the face, something like that of a faded leaf, with minute vessels;—not forming a patch of red, as in hectic fever; but reticulated, like net work, on the cheeks. Where we observe this, there is generally some part of the abdomen in a state of organic disease. We discover, in a moment, the strength of a patient by his countenance. When attending a case of fever, there is frequently no occasion to ask a question: we can tell whether a patient is better or worse, by viewing his countenance. So with respect to many other diseases;—when the patient is getting either better or worse, we can tell immediately, by his face, what change has taken place subsequently to our previous visit. Every body makes this observation; and hence, when an individual meets a friend, he tells him

he looks well, or that he is sorry to see him ill. If the appearance of the face be so characteristic of the state of an individual's health, even in the judgment of an inexperienced person, how much more so must it be in that of the medical man, who studies minutely every shade of change and difference that takes place in each particular part.

Of course, if disease take place in the face locally, it will show itself there as in other parts of the frame;—whether it be swelling, mortification, local cutaneous disease, or whatever else may happen to it.

*The Tongue.*—In the *tongue* an immense number of symptoms present themselves; and the body cannot labour under inflammation in any part, without the tongue becoming affected by it; if there be strength, generally the tongue becomes white. If there be inflammation within the stomach and intestines, it frequently becomes red,—red at the tip, red at the sides, perhaps red all over; and perhaps there are red stripes upon it. If the stomach be simply in a state of dyspepsia, and the bowels confined, the tongue becomes covered with a yellow thick mucus. The indications of the tongue are innumerable; they have been observed from the remotest ages; and no one would think of finishing his attention to a patient, without looking at that organ. The tongue will sometimes become brown; sometimes it will become absolutely black. In what are called “putrid” diseases,—where there is a high degree of debility, and a disposition to putrescency,—the tongue will become black. In other cases it will become glazed throughout, shining, and glassy; and in this state it will frequently be cracked. In other diseases, again,—as in “delirium tremens,”—it is frequently covered by a creamy mucus;—not a thick yellow mucus; but a mucus more like cream than any thing else, and so liquid that the tongue is moist. The tongue frequently, in paralysis, moves to one side; but generally in an opposite direction to that in which the mouth is drawn.<sup>a</sup> In fever, and other diseases, the tremor of the tongue is very characteristic. In general the whole body trembles; but the tongue does so particularly. In “paralysis agitans,” though the person lie still in bed, yet if he put out his tongue, it is seen to be in a great degree of tremor. In cases of dyspnœa<sup>b</sup> and apoplexy, the tongue is swollen. I need not insist upon the great importance of this part of the face or head,—the tongue.<sup>c</sup>

*The Eye.*—Then, again, if we take the *eyes*. We discover, in a moment, whether there is great excitement of the brain going on, by the sparkling of the eyes, by their redness and watery appearance. We can discover whether a person has headache, by the oppression shown in the eyes; and, in some affections of the head, the eyes squint,—are contorted in various ways. Frequently, too, when a person is asleep, he does not completely close his eyes; which is often an indication of disease. Then, again, the state of the pupil is very characteristic of many affections of the head. If we take the eye altogether, there is generally an appearance of brilliancy, or of dulness; or, if we take particular parts, there is a dilatation of the pupil, or (on the other hand) an extreme contraction: all these things it is of the highest importance to observe, because they point out particular affections. For example: if we take apoplexy, we usually see the pupil dilated, and know that there is great oppression of the brain; but if the pupil be amazingly contracted,—reduced to a pin's point, we may almost to a certainty say that the patient will die. I do not say it is *absolutely* certain; because it is wrong to speak positively. If a person have taken a large quantity of opium, there is generally the same effect produced—a great contraction of the pupil; and where

<sup>a</sup> In paralysis of one side of the face, the tongue goes to the *diseased* side;—being turned in that direction, as on a pivot, by the action of the “genio-hyo-glossus” muscle of the healthy side.—*Dr. Fletcher.*

<sup>b</sup> From *δύσπνοια*, with difficulty; and *πνέω*, to breathe.

<sup>c</sup> The tongue is flat, with its anterior extremity rounded, in gastro-enteritis. It is cylindrical and pointed in hectic fever; in which the “lobster-tongue” (red, with white papillæ) sometimes occurs. In scarlatina it is white, with red papillæ. In dyspepsia, especially in the morning, it is rough and scabrous.—*Dr. Fletcher.*

we are not informed with certainty of the patient having taken that narcotic, the appearance I have just described will assist materially in forming the diagnosis. Then—besides the strabismus,<sup>a</sup> and open state of the eye during sleep—there are contortions in various instances; particularly if a child have convulsions of another part of the face,—the muscles of the lower jaw; so that he gnashes and grinds his teeth together during sleep, and his eyes roll.<sup>b</sup>

*Risus Sardonicus.*—There is one set of convulsions about the mouth, mentioned under the term “*risus sardonicus*.” It is a horrid sort of grin, which is often seen in persons who are about to expire. To me it is the most terrible of sights. It has been thought to characterize inflammation of the diaphragm;<sup>c</sup> but I do not know whether that is the case;—inflammation of the diaphragm is a rare affection. It is common, however, for persons at death’s door to grin frightfully. The phenomenon receives its name from a herb, of a poisonous quality, which grows in Sardinia; and is said to produce in those who eat it, this horrid contortion of the mouth, just before death.

*The Orbit.*—From the state of the orbit, or at least the contents of the orbit around the eye, we may judge of the extreme debility, exhaustion, and emaciation of the patient. If the parts around the eye become absorbed, the eye sinks back in the orbit, and there is produced a hollowness, which is characteristic of extreme exhaustion and inanition; and this alone will enable us to say, in a moment, how much worse the patient has become.

*Facies Hippocratica.*—We likewise see a singular appearance of the countenance, mentioned by almost every writer, under the title of “*facies Hippocratica*,” so called, because Hippocrates gave a most accurate description of it. His description is,—“sharpness of the nose; hollowness of the eyes; collapsed state of the temples; collapsed and contracted state of the ears; the edges of the nostrils everted;<sup>d</sup> the skin of the forehead firm, tense, and dry; paleness of the whole face, perhaps even blackness, or a livid and a leaden appearance.” These are the characteristics of the “*facies Hippocratica*.” It is the usual appearance of the face, immediately before death; when the body is at last completely exhausted, and life about to be resigned.

*The Teeth.*—I may mention (although it is not in regular order) that among the symptoms of phthisis, one is taken from the teeth:—not that all phthisical

<sup>a</sup> From σκελεζο, to squint.

<sup>b</sup> The eyes do not close in paralysis, apoplexy, asphyxia, and the “Hippocratic countenance.” An open state of the eyes, therefore, is considered a very bad sign. In tetanus the eyes are generally open, both when the patient is asleep and when he is awake; for neither the sphincter (“orbicularis palpebrarum”) nor the “levator palpebræ superioris” is completely relaxed;—so that the eye-lids are always partially separated. In this disease, the ball of the eye is fixed;—from contraction of the “recti” muscles. Ptosis is a palsy of the “levator palpebræ superioris.” Strabismus occurs in the first stage of apoplexy, in myelitis of the upper part of the spinal cord, in amaurosis, in worms, &c. It takes place either from defective action of one set of muscles, or from increased action of another set. The direction of the eye is upward, in tetanus, because the “inferior oblique” muscle acts too much; and in paralysis and syncope, because the “superior oblique” acts too little. The eye is too moist in tetanus, and the last stage of ophthalmia; it is dry in the first stage of ophthalmia, in phrenitis, and in all the diseases of debility. It appears to “flash” in anger, mania, hysteria, and fever. The cause of this appearance is, that the vessels in the interior of the eye are dilated, and admit more white blood; so that more light is reflected. The iris is said to be convulsed in epilepsy, but I never met with any one who had seen it; and we are not sure that the iris is muscular,—so as to be capable of being convulsed.—Dr. Fletcher.

<sup>c</sup> From δια, through; and φερρω, to divide.

<sup>d</sup> The nostrils are dilated in phrenitis, tetanus, and all diseases of excitement and impeded respiration. They are constricted in asphyxia, and all diseases of depression. This constriction is very remarkable in the “Hippocratic countenance,” which depends on defective muscular action. The “hectic countenance” is distinguished from it by redness of the cheeks. In all other particulars it resembles the Hippocratic; but depends on a different cause;—the absorption of fat. The expansion of the nostrils, in dyspnœa, is not for the purpose of admitting more air; for, if that were the case, the mouth would be open. It is owing to the great stimulus applied to the portio dura; which sets all the muscles supplied by it into energetic action.—Dr. Fletcher.

patients have the same state of the teeth; but in many there is beautiful whiteness of the teeth, with a degree of transparency and brilliancy, comparatively seldom seen in persons who are not disposed to phthisis.

*Exanthematic Eruptions in the Face.*—I may mention that exanthematic and acute inflammatory cutaneous diseases, show themselves much better on the face, for the most part, than anywhere else. It is on the face, first, that we discover a child is going to have the measles. When a child is in a state of pyrexia, and we are sure it is going to be ill of something or other, the face will first disclose it, if it be the measles. There we have the running of the eyes,—there we have the fulness; and the first papulæ that present themselves, are generally seen on the face. Most acute cutaneous diseases attack the face among the earliest parts; or if they do not, yet the face, if affected, generally discovers the true nature of the disease better than any other part; the reason of which is, that the face is much more vascular than other parts. The cheeks are more or less inclined to be red, in most individuals; and the least feverishness reddens the face, more than any other part of the body; and therefore it is that acute cutaneous diseases generally show themselves best in that situation.

*Paralysis of the Face.*—With respect to the face, simply as a part of the surface of the body, we discover paralysis in it more easily than in any other part. If a person be sitting still, we cannot tell whether his arm or his leg is paralyzed; but if his face be paralyzed, we can generally in an instant discover it, by the part affected being drawn to the opposite side, and perhaps from the patient's inability to swallow his saliva.<sup>a</sup> And so with regard to the tongue;—the moment the person begins to speak, we frequently can discover the existence of paralysis.

*The Countenance.*—The face is particularly indicative of the general state of the individual's mind, and of the general state of the strength likewise; and we then, perhaps, should rather call it "the countenance;" and speak of "the countenance" instead of "the face;"—"the countenance" being the term generally used in reference to the state of the feelings. We can judge directly whether a patient is in pain or not,—whether he is suffering, by the countenance. In colic, and in enteritis, the agony is so depicted in the countenance, that we discover in an instant that something must be wrong. I need not say that, in insanity, that passion of the mind which is predominant, discovers itself in the countenance. We may at once detect a good-natured, a furious, a proud, or a desponding maniac. We may also discover much by the way in which his head is carried,—to say nothing of his countenance. Those that are proud, carry the head upright; those that are cast down, carry it the reverse. But the countenance, independently of the position of the head, is indicative of the character of the disease;—an idiot is almost immediately discovered by the expression of his face. We ascertain in a moment, by the countenance, what the person's feelings are with respect to strength as well as to comfort; and what passions of the mind are predominant. We discover, as I before mentioned,<sup>b</sup> whether a person is better by observing his face,—by noticing whether it looks fuller; but we also discover much from the expression of the countenance. What a vast amount of information, therefore, is given by the face;—not only with respect to affections of that particular part, but with respect to all other parts of the body.

*The Attitude.*—A great deal may be learned of the patient's feelings, by the attitude of his body. In fever nothing is a more unfavourable omen, than for a patient to be seen lying on his side at first, and gradually getting on his back, till he lies altogether supine; but when he also sinks in his bed, the case becomes still more alarming. The reason is simply this:—More muscular strength is required in order to lie on the side, than on the back, and to remain in a firm posture than to sink down; and therefore, when a patient sinks down, it is an indication that his strength is nearly exhausted. We discover a great deal, too, by the restlessness of the whole body. One of the most unfavourable symptoms, in many dis-

<sup>a</sup> Probably from "salitus," salt.

<sup>b</sup> See Page 55.

eases, is extreme restlessness. Restlessness, in women, may arise from mere fidgets; but in acute diseases, when great debility has come on, restlessness is often one of the fatal symptoms.

*The Hand.*—But to go to the *hand*;—the part which, together with the face, in all countries (civilized and uncivilized), is most exposed. In the hand we have very great indications; though, certainly, they are not so strong as in the face. The hand is one of the extreme parts, and shows the first fall of temperature. It is one of the first parts that become cold;—exactly as the nose and ears do in the head. I believe the difference between its temperature in fever and in health, is often greater than the difference of the temperature of most other parts of the body. A cold sweat is shown in the hand, among the earliest parts; and the hectic fever which flushes the face, flushes also the palm of the hand, and indeed the sole of the foot; but it is shown particularly in the palm of the hand, from the greater fineness of the integuments. Difficulty of breathing, again, discovers itself by the appearance of the nails. If, in the difficulty of breathing, we observe a purple hue of the lips, a fulness and a leaden colour of the face, and a purplish colour of the eyes, we discover likewise a purple hue of the nails,—at least the parts under the nails. As I mentioned, in jaundice, that the disease appears first at the roots of the nails, as well as in the sclerotica; and that after the disease has disappeared from the rest of the surfaces, we may discover it still lingering in the system by the yellowness observed in the same two parts,\*—so I believe that the changes, with respect to the eyes and nails, go on *pari passu*<sup>b</sup> in dyspnœa. The dryness of the hand, its mordant heat, its clamminess, its firmness, its softness, the very grasp of the patient,—are all significant. If phthisis is often seen in the eye, the ends of the fingers are no less indicative of it, or of some other internal scrofulous affection.

Besides all this, it is in the hand that we easily make the most important conceivable observations, upon the state of the circulation. It is in the hand, or at least at the wrist, that we feel the pulse much more easily than at any other part of the body. The same observation might be made anywhere else; but it would be done far less accurately, and with far less ease, than at the wrist. With respect to all other observations,—about temperature, about heat, about cold, about clamminess, and about sweats,—I think that not only are they all made much more accurately in the hand than in any other part, but that the hand appears to be affected by these particular symptoms, more than most other parts of the surface of the body.

*Volume of the Pulse.*—With regard to the *pulse*, great indications of disease are taken from it. The pulse generally is spoken of, in the first place, as “great” or “small” (“*pulsus magnus*,”—“*pulsus parvus*”); it is mentioned likewise as “strong” or “weak” (“*pulsus validus*,”—“*pulsus debilis*”); and as “hard” or “soft” (“*durus*,”—“*mollis*”). A pulse may be *large*,—may be *considerable*, and yet not *hard*; a pulse also may be *hard*, and yet by no means *large*,—on the contrary, exceedingly *small*. A pulse is not necessarily *strong* because it is *large*: neither is it necessarily *weak* because it is *small* in volume. If a pulse be both *hard* and *large*, it is a *strong* pulse also; if a pulse be *small* and *soft* together, then it must be considered as *weak*. Mere softness may be such as to amount to weakness; and if it be exceedingly weak, we may extinguish it by the least pressure of the finger. This pulse has been called “*pulsus vermicularis*,” and (among us) “fluttering,” if it be also quick. It is a pulse easily recognised in practice; and, in many cases, indicates death to be at hand. If a pulse be exceedingly *hard*, and at the same time *small*, then it has been called “a wiry pulse.” A wire is necessarily fine and hard; and a pulse which has the same attributes is called “a wiry pulse.” This is different from a *thready* pulse; just as thread is different from wire. A *thready* pulse is merely that which is small, soft, and weak;—a vermicular motion, hardly worthy of the name of a pulsation. It is chiefly in violent inflammations of the abdomen, that we have the *wiry* pulse; however, we must not depend upon the

\* See Page 54.

<sup>b</sup> “In similar progression.”

pulse only, in such cases. If there be other symptoms of inflammation of the stomach, or intestines, or peritoneum,<sup>a</sup> we must not say that is not the disease, because the pulse is not wiry.

*Rate of the Pulse.*—These are qualities of the pulse, with respect to its volume, solidity, and force;—*large* or *small*, *hard* or *soft*, *strong* or *weak*. But there are other varieties of pulse, taken from its *rate*. A pulse may be *quick*, and a pulse may be *slow*; there is the “*pulsus frequens*,” and the “*pulsus rarus*.” The pulse will sometimes go up to 160. Sometimes it will go beyond that;—so that we cannot count it, especially if weak. But then we can ascertain the state of the circulation by the heart, where we can count 200 and upwards with perfect ease, when we cannot count the pulse at the wrist. A distinction is made with regard to a frequent pulse, into a “*pulsus frequens*” and a “*pulsus celer*.” “*Frequens*” is where there is a large number of strokes in a given time; and, “*celer*” is where the strokes take place in a short and abrupt manner. “*Pulsus frequens*” and “*pulsus rarus*” are opposite to each other;—the former being a rapid, and the latter a slow pulse. The opposite of the “*pulsus celer*” is the “*pulsus tardus*,” in which, whatever number of beats take place, they occur in a gradual manner. In England, practitioners call the *pulsus celer* “a *jerking* pulse;”—“*jerking*” and “*sharp*” are our terms corresponding to “*celer*,” with regard to the pulse. No matter whether it is quick or not, we say it is a *sharp* or *jerking* pulse; whereas, on the other hand, that which takes place (as it were) deliberately, is called “*pulsus tardus*.”

*Examine the Pulse at both Wrists.*—I may mention the great importance of feeling the pulse at both wrists. If we feel the pulse at the left wrist only, we may often think that the patient, from extreme debility, cannot bear bleeding; but if we feel it at the right also, we can frequently form a very different opinion. Nothing is more common than for the pulse at the two wrists to vary exceedingly; and it is the pulse at the *right* wrist that, in the greater number of cases, is the correct guide. The difference is so great, in so large a number of cases, that it should be a general rule to observe both pulses. I have never myself seen the pulses different in point of *time*; but there is a great difference with respect to *force*. It is also certainly right, in cases of great nicety;—where we are in doubt as to the means to be used,—to examine likewise at the heart; and in cases of local disease of that organ, it is also right to examine the heart itself; for, in some diseases, we have simply, from an affection of the heart, a very violent pulse;—such as would lead us to bleed to a great extent. But, in those cases, the pulse is not an indication of the general strength of the patient; but receives its character solely from the disease of the heart. On the other hand, in some diseases of the heart itself, we find a very small pulse; and, on examining the heart, we hear it beat violently; but, owing to a diminution in the aperture, the blood escapes in small quantity.

*Irregularity of the Pulse.*—I should likewise mention, with respect to the pulse, that its rate, size, and force, are sometimes irregular. It will vary in strength and size, at different beats; and it will also vary in frequency. We sometimes have a pulse merely *irregular*;—beating always with nearly the same *force*, but at an irregular *rate*; and that is an “irregular” pulse, in the common acceptation of the word. But, besides that, we frequently find it irregular in *force*, *size*, and *frequency*; so that it will give a strong pulsation or two; then a number of strokes of no strength at all; and, again, it will beat violently. Irregularity, therefore, does not refer to *frequency* only, but likewise to *force*. Sometimes the pulse intermits.

*The Pulse varies according to Age.*—We must also remember, as physiologists, that the pulse differs in every age,—that the younger we are, the more quick is the pulse; also that the pulse of the female is quicker than that of the male; and that, generally, the inhabitants of a warm climate have a weaker pulse, than those in a more temperate latitude. It is necessary to take all these things into considera-

<sup>a</sup> From *περι*, around; and *τενω*, to stretch.

tion; because, if we were to find the pulse of a child 120, and that of an adult labouring under fever likewise 120, we should commit a great error in supposing that the child likewise laboured under fever. It is necessary, therefore, to remember that the pulse varies according to age, sex, and climate; and that in young children it is particularly quick. I had an instance of the great use of examining a patient in bed, and not being contented without what is contemptuously called “a *mechanical* examination,” in an enlargement of the abdomen:—

*Case.*—I was called to visit a pregnant lady, about thirty years of age, whose pulse was about 80 or 90; but on listening to the abdomen,—she being single, and having some disease (as she said),—there was another pulsation, about 128. The pulsation did not arise from any of the branches of the iliac arteries; for their pulsations would have been the same as at the wrists. She had a pulse of 80; something within her had a pulse of 128; and what that was, I left her to settle by herself. All that I could say was, that if she waited patiently, the whole of the disease would come away, to a certainty, in two or three months.

The pulse has been called, in the most ancient times, “*res fallacissima*,”—the most false of all symptoms; but the truth is, *all* symptoms are delusive, if taken separately: it is the collection which enables us to form our judgment. The varieties which I have mentioned, are sufficient for all practical purposes, and are the only ones that I have observed; but we find, in books, an extreme *minuteness* on this point; and, I think, a great deal of absurd trifling. The Chinese, I understand, have made most minute observations on this subject. They describe all sorts of pulse;—such as (I dare say) no one ever observed, and no one ever will.

As to the two parts of the body hitherto mentioned,—the face (or, rather, the head altogether), and the hand, our observations upon them are chiefly made by sight and by touch. The head and the hand, of course, when they themselves are affected, give all the symptoms common to other parts of the body. When either of these parts is inflamed, the various local symptoms present themselves. It is not, however, of local symptoms that I am at present speaking; but of symptoms indicating the state of the other parts of the system in general.

*State of the Breath.*—However, there is another sense that may be employed with respect to the head; and that is the sense of smell. The breath that proceeds from the mouth, has sometimes peculiar odours; which, if we do not take pains to notice, we are at any rate compelled to observe.

*The Neck.*—To proceed, downwards, however; the *neck* affords a certain degree of information, but not much. A *long, thin* neck is frequently taken, in conjunction with other symptoms, as a sign of phthisis; whereas, a *short, thick* neck indicates a disposition to fulness of the head and chest. The pulse in the neck is also an indication of different diseases. In many affections of the head, the carotids<sup>a</sup> will throb violently,—so as to be seen at a distance; and in many affections of the chest, the same circumstance is observed. Here, again, we see the necessity of attending to more symptoms than one. A great throbbing of the carotids may arise either from an affection of the chest, or of the head; for they both give rise to it. The pulsation of the jugulars<sup>b</sup> is likewise frequently an indication of thoracic disease; for a difficulty in the transmission of the blood through the chest, will give rise to a great pulsation of the jugulars. I need not say, that the tenderness of the neck indicates various diseases. By observing tenderness in that situation, it is frequently easy to ascertain the existence of disease in the larynx; when, otherwise, there might be doubt as to the nature of the affection.

*The Thorax.*—With respect to the *chest*, it affords us a vast source of information. Its size and shape indicate the general constitution. Phthisical patients generally have a narrow and flat chest;—contracted in various directions,—shallow and flat in front, and narrow at the sides. If a person be disposed to apoplexy (from mere plethora and congestion), and in gouty persons, the chest is disposed

<sup>a</sup> From *καρως*, to cause to sleep; because the tying of vessels in question produces coma.

<sup>b</sup> From “jugulum,” the throat;—so called from “jugum,” a yoke.

to be circular. Frequently the chest is deformed; and frequently it acquires an enlargement in various parts, from disease in the pleura. When a collection of water or pus (particularly of pus) takes place in the pleura, it is not uncommon to find that the sides of the chest have become enlarged. It is, therefore, frequently of great importance in thoracic diseases to strip the patient, and look at his chest; for we may frequently discover by the eye a slight deviation in its two sides, which we cannot observe by the touch. A deviation so slight, that it would escape us if we resorted to measurement, is frequently perceptible to the eye.<sup>a</sup> Of course, the touch will give considerable information with respect to tenderness; and also with respect to the state of respiration, and the state of the heart,—by the thrill which we experience. In some cases of difficulty of respiration, we find under respiration a thrill; and in certain obstructions of the heart itself, we find, on pressing over a part of the heart, a similar circumstance takes place,—corresponding with the action of the heart. In some cases of aneurism<sup>b</sup> of the aorta,<sup>c</sup> and of diseases of the heart, we find by the hand a strong pulsation.

*Respiratory Sounds.*—But although the sight and the touch give this information, there is a third sense which imparts especial aid with respect to diseases of the chest; and that is hearing. The function of the lungs differs from the function of many other parts, in this circumstance.—It is performed with a noise; and so, likewise, is the function of the heart. The functions of the brain and the liver go on without any indications appreciable by our senses; but it is peculiar to the function of the lungs and of the heart, that a certain sound should take place. If this noise take place in health,—in sound physiology, it must be expected that when the function of these parts is disturbed, the *physiological* sound will become *pathological*;—that the sound will be altered; and such is actually the fact. If this be the case, it is our duty to attend to it; if it be not the case, let those who say so prove that they are correct. We declare it is so; and we ask those who entertain a contrary opinion to listen for themselves.

*Indications furnished by Percussion.*—As to the lungs, it will sometimes be found that the healthy sound of respiration ceases altogether. A lung becomes impervious at a certain part;—the air will not go through it; and this may arise from an obstruction to the course of the blood into the lung. But it may also arise from the lung itself becoming consolidated; or from external pressure of the lung;—the dropsical pleura preventing the lung from expanding. We may thus ascertain, however, that respiration is not going on in that spot. Besides an absolute want of sound, in certain diseases of the chest, there is in others an *unnatural* sound;—the sound of respiration does not *cease*, but becomes strangely *altered*. Information is afforded, not by listening only, but by *striking*. If the chest be struck, the lungs in health give out a hollow sound. The lungs being filled with air, a hollow sound is necessarily produced. If something takes the place of air;—if the lungs become consolidated, or filled with fluid, or surrounded by it,—it stands to reason that, if we then strike that part of the lung, the air being absent, a dull sound will result. This is actually the case. These things are physical necessities;—they occur simply from the common law of physics.<sup>d</sup> They must occur; and if they do, we ought to apply them to practical purposes.

Nothing, however, would be more absurd than to attend to these auricular symptoms solely. The fault of those who merely employ the ear, in diseases of the chest, is just as great as the fault of those who do not employ it all. There may

<sup>a</sup> The chest may be *enlarged* from collections within of air, water, or pus. It may be *contracted* (generally on one side) from pleuritic adhesions, and after paracentesis. Adhesions of the pleura cause difficulty of breathing in the lung to which they correspond; so that the muscles on the affected side are not used so much as on the other. This causes, on that side, a diminution of bulk.—Dr. Fletcher.

<sup>b</sup> From *ανευρυσμα*, to dilate.

<sup>c</sup> From *αἷμα*, air; and *τηναι*, to keep;—the vessel in question being supposed, by the ancients, to contain air alone.

<sup>d</sup> From *φυσικὴ*, nature.

often be a sufficient number of other symptoms to point out the nature of the affection, without employing the ear; but whether that be the case or not, it is as much our duty to attend to other symptoms, as to those that we learn from the ear. Frequently, by looking at a patient while he is breathing, we find what is the state of respiration. We find that, like the pulse, it is more frequent than natural, or not so frequent as natural;—we may have the “*respiratio frequens*” and “*respiratio rara*,” corresponding with the “*pulsus frequens*” and “*pulsus rarus*.” Now and then we find respiration performed suddenly;—the inspiration and the expiration are sudden; and that is called “*respiratio celer*,” and the opposite state, where the chest expands slowly, is called “*respiratio tarda*,”—corresponding with the “*pulsus celer*” and “*pulsus tardus*.” These things may be learned simply by the sight. The respiration undergoes alterations similar to those of the pulse;—it may be *regular* or *irregular*, *slow* or *quick*, *sudden* or *gradual*. It may be *deep*, or exceedingly *shallow*,—little air being taken in at a time; and, on the other hand, we may have a *full* respiration. It may be *full* and *deep*;—corresponding with a full and strong *pulse*. I do not mean to say, that the pulse and the function of the lungs take place synchronously; but, as we have in the pulse quickness and slowness, fulness and smallness, jerking and sluggishness,—so in respiration we have frequency and slowness, shallowness and depth, suddenness and sluggishness, irregularity, and so on.

*Dyspnœa and Orthopnœa*.—When respiration takes place with difficulty, it is called, in medical language, “*dyspnœa*,” and if it be so difficult that the patient cannot breathe unless he sit upright, it is called “*orthopnœa*.”<sup>a</sup> *Orthopnœa* is merely an intense *dyspnœa*.

*Respiratory Sounds*.—Independently, however, of the *frequency* of respiration or its *slowness*, we may hear particular sounds. We may hear a *wheezing* sound, which is called “*sibilous*,” or we may sometimes hear it performed with a *snorting* sound, which is called “*sonorous*.” Even without putting the ear to the chest, or employing a piece of wood as an intervening substance, it may sometimes be heard when standing at a little distance.

*Alterations in the Voice*.—The *voice*, also, affords much information. The voice is frequently suppressed, faint, harsh, and shrill; and these various changes will indicate great debility; or they will indicate particular diseases of the lungs themselves, or of the larynx, or of the air-passages. From listening to the voice, —with the ear in contact with the chest, or with the intervention of a piece of wood, or any similar substance,—frequently the voice does not afford the ordinary sound; so that some disease may be predicted to exist within the lungs.

*Cough*.—From a *cough*, too, we learn much with the naked ear; and the varieties generally enumerated are “*slight*,” “*severe*,” “*harsh*,” “*crowing*,” “*hooping*,” “*shrieking*,” “*tearing*,” “*hacking*,” “*loose*,” and “*dry*.” There is an infinite variety with respect to coughs. “*Slight*,” “*severe*,” “*crowing*,” and “*hooping*” varieties, about which I need not say any thing. We occasionally hear a cough “*tearing the patient to pieces*,” and it frequently indicates more disposition to spasm, than to actual inflammation. Now and then I have heard a cough, which has been regularly followed by a shriek, and absolutely alarming. At the end of every set of expirations, I lately heard one deep inspiration, not attended by a hoop (as in the *hooping-cough*), but by a shriek;—as though the individual were about to have a dagger plunged into her.

*Alterations in the Heart*.—With regard to the *heart*, we obtain great information by examining the chest. For only by the touch can the force of the heart be ascertained; but by listening, the various alterations in its sound may be heard. Here, again, it is very necessary not to attend to any one system, or to the occurrence of any one sound; but to attend to the whole set of symptoms. Instead of the usual double sound which is heard in a healthy person, when the heart is affected in a certain way, we hear a sound as though a pair of bellows were blow-

<sup>a</sup> From *εἰθε*, erect; and *πνεω*, breathing.

ing; sometimes as if a file were in action; and sometimes as if a substance were being rasped. If we attend to these alone, we may be led into error; but frequently, at the same time, great difficulty of breathing is observed on the slightest motion; also a swelling of the legs, and a deficiency of urine; and we are led to believe that organic disease is present. In other cases we hear only the sound; and then we should not be justified in saying there was organic disease, unless it is observed time after time. In observing these sounds of the heart, the greatest care is necessary not to form a hasty judgment at first. We may also observe a sufficient proof of organic disease, by attending to the general symptoms; but frequently there are no other circumstances present. These sounds may arise from temporary causes, and not be heard on two successive days,—showing that these symptoms,—like those of the pulse, and almost all other symptoms,—are never to be taken alone, but only in conjunction with others; and, then, only when they have been examined carefully and repeatedly.

*Abdominal Signs.*—With respect to the *abdomen*,—to descend still farther,—the chief symptoms in that region are to be observed by the sight and touch. The hearing affords no great information respecting the abdomen, except sometimes on striking it, if it be enlarged. If we strike it,—especially with the intervention of some little substance (either the finger or a piece of ivory),—we learn whether the tumour arises from liquids or solids, by its emitting a dead sound, as if we struck the thigh; whereas, if it arise from mere air, there is a hollow sound, like that of a drum. By going over the abdomen carefully, we may ascertain whether there is enlargement of any organ, and we ascertain the shape of an enlarged liver with the greatest accuracy;—the dulness occurring where we strike, over the enlarged organ, and the hollow sound, where the abdomen is in its natural state. This is the only point in which the ear is of much assistance. The ear is of the greatest use in diseases of the chest; but in the abdomen we must more particularly have recourse to sight and touch.

If we expose a patient, in the case of abdominal disease, we may discover an alteration of figure which the hand cannot at once detect. Nothing can be more absurd than for a practitioner to prescribe, at once, for a patient who comes to his house for disease of the chest or of the abdomen. It is very well to prescribe in that way for diseases of the skin, the head, and other affections; but with respect to diseases of the chest and the abdomen, if we do not listen, or have the patients more or less undressed, it is impossible, in many cases, to form a correct opinion. We may form a guess, and we may be right; but shall not be able to form such an opinion as a philosophic mind would always wish.

With regard to the abdomen, by the sight we may discover enlargement, either local or general; but it is certainly by the touch that we acquire the greatest information. We may feel an enlargement of various parts; we may feel the induration of different viscera; and if there be fluid, we may ascertain its existence by the occurrence of fluctuation. But one great use of applying the hand to the abdomen, is to ascertain the existence of inflammation. Inflammations of the abdomen are, in general, easily detected by the hand pressing upon it;—owing to the circumstance of the abdomen having no bony coats; and it is always necessary, in acute diseases, carefully to examine the abdomen by means of the hand. In fever, and particularly in various affections of the alimentary canal, if we do not examine the abdomen carefully with the hand, we may overlook inflammation; which, if neglected, may prove dangerous. In fever, at any rate, it is right (every day or two) to feel the abdomen carefully;—beginning at the epigastrium (which is the part most frequently affected), and going more or less all over it. But in every case where the abdomen is affected, it is of the greatest importance to make these minute observations. It is nonsense to say that a physician is to use his pen, and a surgeon his hand. Every physician must be more or less a surgeon, and every surgeon must be more or less a physician. It is as impossible for a physician to do without the use of his hand, in the case of the abdomen, as it is for a surgeon in the case of fractures; and it is not creditable to any physician to

pride himself upon not making these “*mechanical examinations*,”—as (I believe) they are contemptuously called.

*Characters of Excretions.*—With respect to the *excretions* of the body, the sight and the smell give us the chief information. It is only by the sight that we judge, chiefly, of the character both of the *fæces* and the urine; the smell, however, gives certain information in these particulars; as it also does with regard to the excretion of sweat. The sweat, in many diseases, is exceedingly sour; and in others it has peculiar odours, of which I shall speak hereafter. However, we sometimes are more minute in our observations respecting the urine. At any rate, it is necessary not to depend upon the sight and the smell merely; but to employ chemical means for ascertaining its quality. It is frequently requisite to ascertain whether the urine is acid, or neutral, or alkaline; it is right, frequently, to see whether it contains albumen or not; and, in other cases, it is necessary to ascertain whether it contains sugar. The most minute observations are sometimes necessary; and, of course, it is only with respect to the excretions that chemical minuteness is at all of service.

As to one sense,—that of taste,—I believe it can only be employed with regard to excretions; and, I presume, with but one of them,—the urine. Some go so far, in professional enthusiasm, as to wish us to taste every thing; but it is not usual except in case of the urine; and then, for the most part, it is better to get the patient to taste for himself. However, this is not *absolutely* necessary with regard to the urine; because, by evaporation, and by weighing the urine, we can easily ascertain whether it contains sugar or not. I never yet in my life tasted it; but I have no objection, in diabetes, to taste the saccharine extract; for that is not urine.

*Alterations in the Surface of the Body.*—Having gone through the chief organs of the body, I may say that the *whole surface* together gives the same information as the head; but in a very inferior degree. We gain certain information; but it is, undoubtedly, far less than we gain from inspecting the face. From examining the whole body, we learn whether there is a degree of fulness or emaciation. By observing its plumpness, we can tell whether the patient is in condition or not. We observe, likewise, the dryness or moisture of the skin, and the firmness of the flesh. We observe whether or not it is swollen by dropsy. It is to the surface of the body that we employ the sense of smell, with regard to the excretion of sweat. On the surface of the body we can ascertain the increased temperature of the patient; and, for more minute observation, a thermometer is employed. It is generally put into the *hand*,—one of the two principal parts; or put under the tongue,—a portion of the *head*. Every part of the surface of the body has its own affections; and it is there that not only the chief symptoms of cutaneous diseases,—the symptoms of all its own affections, are to be found; but there we often observe affections of parts beneath. In inflammation, for example, of the *dura mater*, from an injury, the surface immediately above frequently becomes *œdematous*. We learn the state, not only of the skin itself locally, but of parts beneath it, by looking at the skin immediately superjacent.<sup>a</sup>

*Therapeutics.*—These are the chief observations which I have thought it necessary to make, in a general way, on the third branch of general pathology, called “*semeiology*,” or “*sympmatology*.” The fourth division of general pathology is “*therapeia*,” or the general treatment and prevention of diseases.

<sup>a</sup> The skin is pale, rough, and dry, (forming the “*cutis anserina*,”) in the cold stage of fever. It is pale, but not rough, in syncope. In the hot stage of fever it is red; and its temperature is likewise much raised, especially in scarlatina. The skin is green in chlorosis, yellow in jaundice and yellow fever, and sometimes blackened from the internal administration of nitrate of silver. It is dry in diabetes and dropsy, has an acid odour in military fever, and in ramollissement of the brain its odour resembles that of a mouse.—*Dr. Fletcher.*

## SECTION V.—GENERAL TREATMENT OF DISEASES.

*Vis Medicatrix.*—With regard to most diseases, nature has a constant tendency to rid herself of them. It is ordained by Providence, to a great extent, that the injurious causes to which we are exposed should have but a temporary effect. Either the body has the power of resistance, or the causes exist temporarily; either from being applied but temporarily to the body, or from being able to exert no more than a temporary influence. In this way it is that, generally speaking,—although there are many exceptions,—there is a tendency to shake off disease. This power of the body to shake off its morbid state, is called by writers the “*vis medicatrix nature*,”<sup>a</sup> or *autocrateia*.<sup>b</sup> For example: if any thing too acrid be taken into the mouth, a great flow of mucus and saliva is the consequence; which has a tendency to dilute the acrid matter, and wash it away. So with respect to acrid matters taken into the stomach;—the stomach has a tendency to reject them; or if they be passed through the stomach into the intestines, the intestines are excited to action, and they are got rid of. This is the general tendency of the frame.

*Temporary Diseases.*—Again; many causes of disease are only temporary. A person is exposed to a great cause of disease;—the cause ceases; and of course, in many instances, the effect ceases likewise. It is not a necessary consequence, however, that the effect should cease because the cause is removed; but it very frequently happens thus. Again: there are other causes which cannot produce an influence upon the body, however long they are applied, for more than a certain period. If we take the poison of small-pox, it produces a disease of only a certain duration. The patient may die; but if not, the disease can only last for a certain time; and when it has once occurred, the body, in the greater number of cases, becomes insusceptible of it again. These are the various means which nature has provided for getting rid of disease;—for getting rid of noxious causes before they produce actual disease; and for getting rid of diseases themselves.

Some have so great a confidence in nature, that they leave every disease to itself; and that sort of treatment is called “the medicine of expectation” (“medicine expectante”). Such treatment often does well;—it is the best in many cases, both medical and surgical; but it is totally inapplicable to a large number. No one, with a violent inflammation of the lungs, would consent to sit down quietly, in the hope that he would grow better day by day; when he knows that, by the lancet, he may obtain immediate ease, and get rid of the complaint. When a person has taken poison into his stomach, of course he would be mad to wait for nature to effect a cure. He would send for the physician’s medicine, or for the surgeon’s stomach-pump.

*Prophylactic, Curative, and Palliative Treatment.*—The treatment of the diseases of the human body is either “preventive” or “curative.” We either attempt to prevent disease from occurring, or we attempt to remove it; and when we cannot remove it, we attempt to palliate it. The treatment of the human body, in the way of preventing its becoming the subject of disease, is called “prophylactic;”<sup>c</sup> that which attempts to cure disease, is called “curative;” and when we cannot attempt to cure a disease, still we may do a great deal in the way of palliation;—so that medicine is “prophylactic,” “curative,” and “palliative.” It is very often a great point to enable a person to live (while he *must* live) in comfort and happiness; and if he must die, it is a great point to enable him to die easily. In many cases we have to adopt both curative and palliative treatment together;—that is to say, we aim at curing the disease; but we adopt palliative measures, all the time, for the purpose of lessening any one symptom, or particular symptoms, which it is a desirable object to get rid of, or lessen, before the cure of the disease enables us to do so. For example: in the case of inflammation of the lungs, although we may attempt

<sup>a</sup> “The curative power of nature.”

<sup>b</sup> From *αυτος*, *itself*; and *κρατειν*, *to govern*.

<sup>c</sup> From *προ*, *before*; and *φυλασσω*, *to defend*.

to cure the disease by bleeding, it is sometimes of the greatest importance to put an early stop to a violent cough, by a narcotic.

*Rational and Empirical Treatment.*—We can hardly be said to treat disease, when no disease exists; but we must allow an extended use of terms. Whether our means, then, are to *prevent* diseases (“prophylactic”), or whether they are to *cure* them (“curative”), or whether they are to *palliate* them (“palliative”),—the means in question may be of two kinds, “rational” and “empirical.” In the treatment of many diseases, as well as in their prevention, we act *rationally*;—we proceed upon general principles; and the whole treatment is in the highest degree philosophical. We make an accurate diagnosis, in the first instance; we then see what is the wrong state of the system, and employ such means as are evidently calculated to remove that state. But in certain diseases, and in certain varieties of disease, we are obliged to act *empirically*;—to act in a certain way, without knowing why we are likely to be successful.

This empirical mode of practice is of two kinds. Sometimes we have a specific remedy for a disease, without knowing why; and, in other cases, it is impossible to know the exact variety and character of the disease; and we fire at random a shot that can do no harm, but which may do good. The treatment of inflammation is in the highest degree “rational;” the treatment of various spasms is the same; and the treatment of continued fever, too, I must think altogether “rational.” The treatment, however, of ague, of itch, and of syphilis, is “empirical;” for it is impossible to know why a few grains of sulphate of quinine cure ague; why a few grains of sulphur will cure the itch; and why syphilis will cease sooner if we exhibit mercury, than if we do not. No one would *à priori* imagine, that any of these remedies could have such a peculiar property. There is nothing in the nature of the disease, or in the nature of the remedy, that would lead us to any such conclusions. We are also frequently obliged to be “empirical,” where we cannot ascertain the proximate cause of a disease. For instance: epilepsy arises, in innumerable cases, from an unknown cause situated in the head, or in distant parts. If we can ascertain that it arises from irritation, our treatment is “rational;”—we remove the cause. If we can ascertain that it arises from an inflammatory state of the system, our treatment is “rational;”—we remove the cause. But sometimes we cannot conceive that it arises from either of these sources; and then we use certain remedies that are known occasionally to do good;—not that they are a specific against epilepsy,—as bark is against ague, or sulphur against itch; but because they continually do good in the disease. They are not specifics; for often they will not cure one case out of many; and in many cases they are totally inapplicable; but still they frequently do cure the affection. I allude to copper, zinc, nitrate of silver, &c.

*Indications and Contra-indications.*—The mode of treatment which is pointed out, from the circumstances of the case, is called the “indication;” and things which the nature of the case forbid us to do, are called “contra-indications.” To discover the indications which are necessary in the treatment of a disease, we must make a careful diagnosis of the nature of the case; then we must make an equally careful diagnosis as to the variety of the particular disease; and then ascertain the stage of the affection, the exact strength of the patient, and the incidental circumstances. For example: we ascertain whether the place in which he lives, at all accounts for his disease, or whether the season of the year is such as is likely to have affected him. We must likewise observe whether there is any peculiar “constitution” of the period. Sydenham used to mention the character of epidemics as “the constitution of the year.” Continued fever has sometimes been attended by so much tendency to debility, that evacuations were in the highest degree improper; and the patients did much better when they were merely allowed to take simple food, with scarcely any other treatment. This was the case during several months of the year 1831. If the patient was left alone, or treated with what (in truth) was no treatment at all, he has in most cases done well. If the least evacuation was attempted, the disposition of the disease was to great prostra-

tion of strength and rapid sinking. It is necessary, therefore, to know the constitution of the period; and, but for this, I certainly should have destroyed many patients, by treating them as I had been accustomed to do. However, I was warned by the experience of others, and by careful observation of what was going on.

*Individual Peculiarities.*—It is necessary, also, to know what are the contraindications;—whether there is any peculiarity in the patient. Some patients will not bear a remedy which is very appropriate to a disease. The disease may appear evidently to point out the necessity of a certain mode of treatment; but a peculiarity in the individual may render it exceedingly improper. This peculiarity sometimes relates not only to particular medicines, but to particular articles of food; and sometimes there may be some other disease present, which forbids the employment of a particular remedy. For example: if a person have a hernia which cannot well be kept up, we should try to do without an emetic, lest we should force the intestines down too violently. We are not, therefore, to be satisfied when we have given a name to a disease. It is a great point to make a good general diagnosis; but that will not do alone. We must make a more accurate diagnosis still; we must ascertain its minute variety, individual peculiarities, and all the other circumstances that I have just now mentioned.

*Regimen and Drugs.*—The indications of treatment are generally divided into two classes,—“regimen” and “pharmaceutical means;”—the former consisting of injunctions with regard to the temperature of the place,—to food, exercise, rest, and every thing of that description; and the latter respecting drugs.<sup>a</sup> In prescribing medicines, it is necessary to recollect that, however excellent they may be, they are frequently rendered abortive by our want of attention to something else. There can be no doubt of the use of a large number of remedies,—both drugs of the Pharmacopœia<sup>b</sup>, and other remedial means; but I have seen them fail, not through any fault in themselves, but through something else that was not attended to when they were employed. For example: if mercury be given to arrest a violent acute inflammation, we cannot expect it to have that effect if we neglect to bleed the patient; and even though, in addition to giving mercury, we do bleed, we cannot expect to succeed unless we are particular with regard to diet. So, in diseases of the skin, there are many remedies which have a particular operation which we cannot explain. They are not exactly specifics; but they do great good. Yet the skin, in the midst of these diseases, may be in an inflammatory state; and if we do not bleed and enjoin low diet, we cannot remove the affection. As no one *symptom* can be depended upon, so it is with *remedies*; and when we prescribe a remedy for a patient, we must take into consideration all the other points on which it is necessary to give directions.

But notwithstanding the most scrupulous attention to all the circumstances I have just enumerated, we shall often be disappointed in the cure of a disease; but we are not to be dismayed on that account. Our profession is capable of effecting the greatest good in the prevention of disease. By improvements with respect to cleanliness, with respect to air, with respect to food, and every thing else of that description, diseases which formerly prevailed to a great extent are now scarcely known; and we can do absolute good, to a large amount, in curing disease when it has occurred. A great many diseases are inflammatory, and over inflammation, by means of bleeding and other remedies, we have the greatest power. When we cannot eradicate a disease, still it is of great importance, and it is also a great blessing, to be able to mitigate pain; and it is to be remembered, that although we fail in the cure of many affections, yet, if we make the attempt, more knowledge will be attained by degrees; and those who follow us will be able to do what we cannot.

<sup>a</sup> The indications of cure are of four kinds:—1. Prophylactic. 2. Curative. 3. Palliative. 4. Conservative. Those comprised under the last head are designed to guard against a relapse. We fulfil these indications by three classes of remedies:—1. Dietetic. 2. Pharmaceutic. 3. Surgical.—*Dr. Fletcher.*

<sup>b</sup> From *φάρμακον*, a medicine; and *ποιῶ*, to make.

I have now made the chief preparatory remarks which I deemed necessary, before entering upon the consideration of particular diseases,—upon “*special pathology*.” I have confined myself to an exceedingly superficial view of the subject of “*general pathology*,” and to the explanation of a few of those terms which I shall most frequently have occasion to employ. More minute remarks I shall reserve till a subsequent period. For example: when I come to speak of the causes of inflammation, I shall particularly dwell upon the *modus operandi* of various changes and degrees of temperature in producing disease; and when I come to speak of diseases supposed to be contagious, I shall enter upon the subject of contagion. I think it much better to treat these matters in this way, than to treat them in the abstract before entering upon particular diseases; for by this means they will not only be better understood, but we shall be relieved from the tediousness of dwelling long at a time upon general subjects.

## SECTION VI.—METHODICAL NOSOLOGY.

*Methodical Nosology.*—I mentioned that one part of general nosology, or one part of general *pathology*,—one branch of that part of pathology which is called “nosology,” is the arrangement of diseases.<sup>a</sup> One branch (if I may so speak) of “general nosology” is “*methodical nosology*.” We frequently hear the arrangement of diseases spoken of simply as “nosology,” but that is incorrect. The arrangement of diseases is not simply “nosology,” but “*methodical nosology*,”—“*nosologia methodica*.”

It was long before an attempt was made to arrange diseases. I believe Felix Platerus was the first who struck out the idea of arranging diseases methodically; he was followed by Baglivi, an Italian physician, and Sydenham. However, it was a French physician who first actually arranged them systematically;—Sauvages, who published his work in 1762. It was in that year that the first methodical nosology was presented to the world. After him came the celebrated Linnæus, who arranged every object in nature. He published his “Nosology” in Sweden, in 1763. Another physician, Vogel, published one in 1764. No sooner was the thought put in practice, than every body went to work. The arrangement of Cullen was published in 1769;<sup>b</sup> another was published by Dr. Macbride, and one by Sogar, at Vienna, in 1771; then one by an author named Vitenus; one by Dr. Thomas Young, the celebrated English philosopher; and one, still more recently, by Dr. Good. There have been others, but these are the chief.

Now, however useful it may be slightly to arrange diseases,—for the purpose of memory, and for the purpose of general views,—I think it must be confessed, that all these various “methodical nosologies” only perplex and encumber the mind. I formerly studied the arrangement of Dr. Cullen very minutely, and had great part of it at my fingers’ ends; but I confess that my knowledge of it now is but of a very superficial kind, and that it was never of any use to me. The arrangements of Drs. Young and Good appear to me just as useless; and I would not advise others to plague themselves about nosological arrangements. My own experience tells me, that it is a much greater plague to recollect the arrangement, and all the hard words, than to recollect the things for which the arrangement is made. I never found it of the slightest use;—any more than the barbarous jargon of the “*Propria quæ maribus*,” and “*Quæ genus*,” of the Latin grammar.

*Inconsistencies of Nosological Arrangements.*—On the inconsistencies and defects of these various arrangements, I will not dwell; for if we turn to any methodical nosology, we shall find them in sufficient abundance. We find exceptions made to the plan which the author has laid down in his arrangement; and we find the most gross absurdities. If we turn, for example, to Cullen’s arrangement, (which is one of the best,) we shall find that a large number of diseases, which are daily

<sup>a</sup> See Page 38.

<sup>b</sup> See Note to Page 37.

occurring, have no place in it. Such was his arrangement, that not only was there no place for many most important diseases, but he arranges itcl and fracture together. But although I think little of Dr. Cullen's arrangement, there can be no doubt that it was far better than that of any of his predecessors; and I must be allowed to pay a tribute of respect to his memory, as one of the most sagacious and best of men, that ever joined themselves to our profession. I should be very sorry to endeavour to captivate the minds of any, by attempting to lower any one in their estimation. Nothing can be more contemptible; and, as regards Dr. Cullen, nothing could be more unjust. We find in his work the utmost candour, and the soundest information; and although he indulged in hypotheses to which some Scotch physicians have been prone, yet, independently of that, his descriptions are elegant and simple, and his definitions admirable. It is to be remembered that his work on the Practice of Medicine, was not considered by him a perfect work; and he modestly called it "First Lines,"—a mere outline; but such as they are, we shall find them, according to the information of that day, exceedingly useful; and it is on account of the excellency of the original work, that I should perhaps prefer recommending an edition of Cullen, with notes, before the work of any other individual.

*Dr. Elliotson's Arrangement.*—An arrangement is certainly useful; although I am not an advocate for a *methodical* one (so called); and in my opinion, the most natural mode in which we can attempt to arrange diseases in our mind,—that which serves best for the purposes of recollection, is a twofold arrangement; first, as to the nature of affections in general,—whether they are inflammatory, structural, functional, mechanical, or parasitical; and then, secondly, as to the part in which the affection occurs. This is the arrangement which I shall follow. I shall first consider general diseases,—such as affect every or most parts of the body;—inflammation, scrofula, and various other organic diseases;—and afterwards, having considered all the affections which may attack any part of the body, I shall proceed to consider those affections and all others, whether functional, mechanical, or parasitical, as they attack the body from the head downwards, *a capite ad calcem*.<sup>a</sup> I think we all make two inquiries, in considering any case;—the one is the *nature* of the disease, and the other is the *situation* of it. This is the utmost assistance, I think, that the memory can have from arrangement; and this is the plan which is continually followed by *practical* writers. They write on particular diseases, whatever they may be (inflammation, cancer, &c.); and of the whole diseases of particular organs, and sometimes of particular regions. One writer publishes a work especially on diseases of the urinary organs; another, entirely on diseases of the nervous system; another, entirely on diseases of the head; another, on diseases of the chest; and this course we naturally fall into. But, independently of that, we must make observations upon the general affections to which all parts of the body are liable. I am quite satisfied that an arrangement of this sort,—by which we first consider general affections, which may attack any one part of the body; and then consider the affection as seated in this or that part,—will afford us all the assistance that arrangement can give; and I hope we shall never plague ourselves farther with methodical nosology.

<sup>a</sup> "From head to heel."

# PART I.

## GENERAL DISEASES.

### CHAPTER I.

### INFLAMMATION.

INFLAMMATION,<sup>a</sup>—the first disease of which I shall speak,—is the most general of all affections.

*General History.*—It will attack any part of the body that is vascular. It is also one of the most frequent affections. It is a disease which scarcely any person escapes, and which is seen every day. It sometimes occurs simply by itself; and sometimes it is the concomitant of a variety of other diseases. Many diseases are always inflammatory, though they are not simple inflammation;—though there is something more than inflammation, yet inflammation is united with them. Many other diseases are *frequently* inflammatory, but not *always*. Inflammation continually occurs as a means of benefit to the body. It is not only a morbid process; but a process frequently set up by nature for the purpose of restoration, relief, and prevention. It is a disease, too, which proceeds from a vast number of causes;—causes to the action of which we are continually exposed, whether we will or not.

*Its Protective Power.*—Inflammation is the process frequently employed by nature, to prevent the escape of matters into parts where violent inflammation would be produced; and it is established to prevent its own occurrence in another spot. For instance: when an ulcer takes place in the stomach or in the intestines, if it proceed unchecked, the contents of the stomach or the intestines are poured forth into the cavity of the peritonæum, and a violent inflammation is set up;—an inflammation, in the general number of cases, fatal. Nature, however, very frequently excites inflammation outside the organ, exactly at the part corresponding to the ulceration within; by which means it is glued to the surrounding parts. The blood becomes retarded in its course through the neighbouring capillaries, and the surrounding textures become loaded with a glutinous, serous fluid; in which, subsequently, progressive changes occur, and end with its more or less perfect organization. By slow gradations, there take place in it transitions which indicate that the other constituents of the blood have exuded through the vessels; and a part of the fluid effused assumes a gelatinous consistence;—forming layers, or flakes, which gradually acquire complete solidity and organization. This is the interesting process by which the surrounding parts are agglutinated; and the extension of the disease of the stomach or intestines, by ulceration, into the peritonæal cavity, is effectually prevented. Thus, a slight inflammation is set up in one spot, to prevent another, which would be fatal to the patient. The adhesion of the stomach, sometimes to the peritonæum, and sometimes to the liver, is thus explained.

Nature, further, frequently employs inflammation to give exit to something which is injurious to the body. When a biliary calculus is impacted in the ducts, and is

<sup>a</sup> From “*inflammo*,” to *inflame*, or *burn*.

too large to escape, it sometimes happens that these ducts become attached, by inflammation, to the duodenum or other intestines. The inflammation, after it has excited adhesion, proceeds, perhaps, to ulceration; and when the latter occurrence has taken place, the calculus escapes through the opening into the intestines. The inflammation, in the first place, is set up to prevent the communication which would afterwards take place in the peritonæum;—so that the bile and the calculus shall not escape into it; and when all these parts are firmly glued together, and the danger prevented, then, at the particular spot, inflammation goes on to ulceration. Ulceration takes place into the intestines; and in that way an exit is given to the foreign body.

*Its Sanative Power.*—When a part of the body mortifies, whether through inflammation or not,—when a part has become dead, and useless to the body, and even injurious to it from its presence,—inflammation is employed for the purpose of separating it. At the boundary of the living part, inflammation occurs; a red line appears at the extremity of the healthy part, where the dead part begins; which indicates the circular course of the inflammation, and which afterwards proceeds to ulceration. A furrow of ulceration takes place; until the part is ulcerated through, and the dead portion falls off;—having been separated by the ulceration of the living disease.

[There is nothing in the whole domain of medical science, which brings under our view phenomena of greater wonder and perfection, than those processes by which, through the agency of inflammation, nature oftentimes averts impending death. By elaborate and numerous dissections, Abercrombie has shown that a portion of coagulum of blood, extravasated into the substance of the brain, passes through a curious series of changes, both in consistency and colour, before the work of recovery is completely accomplished.

Physiology teaches, that whenever blood passes beyond the limits of the living vessel, its *vitality* becomes extinct; and that it undergoes certain changes;—separating into its elementary parts, in obedience to common physical laws. The aggregate result of these changes in healthy blood, is called “coagulation;” which, in a subsequent page, will have a full explanation. When, therefore, an extravasation of blood takes place into the hemispheres of the brain, or into the expanding track of the *crura cerebri*, or *corpus striatum*,—its most frequent situations,—the process of spontaneous coagulation indicates the death of the blood. In consequence of the pressure of the circumjacent mass, there is not a perfect separation between the serum and crassamentum;—the latter containing within its substance a large proportion of serosity, which renders the clot loose and flabby. It is evident that the presence of this extraneous coagulum in a living structure, must determine that action by which the work of reparation is commenced, and in less severe cases wonderfully completed;—circumscribed inflammation immediately occurs in the brain surrounding the deposit of blood.

The continuance of it in a subdued degree, for some time, enables the surrounding parts to effectually protect themselves against the influence of the foreign matter;—by forming a circular wall of membrane; called, in surgery, the “*pyogenic*,”—from its reputed property of secreting pus. When this is being formed, it is obvious that the pressure of the coagulum against the brain in immediate contact with it, and the surrounding inflammation, must conspire to cause a breaking down of the medullary matter;—it is accordingly found, that a cavity is formed for the reception of the clot; which is limited by the membrane of which we have spoken. Provided the clot be small enough to be compatible with the continuance of life, the paries of the cavity begins its function;—that, namely, of carrying away, by absorption, the contained blood. The serum first disappears,—leaving three portions of different colour;—the thicker yellow part of the serum,—the fibrin,—and the red particles. A ready explanation is here found of the various shades of colour, which the effused blood presents in the progress of absorption. The combinations of these three portions, would produce a compound colour, approaching black or dark yellow; and a variation in the proportion of any one or two, would necessarily

cause a corresponding variation of hue. Thus, then, these interesting appearances are accounted for. The clot subsequently disappears altogether, and the cavity becomes occupied by a serous fluid,—the produce of its membrane; since it does not resemble the serum of the blood. Afterwards, this serum itself disappears, and leaves the cavity empty. By the pressure of the superincumbent mass, the walls become approximated; adhesion occurs; and thus obliteration and recovery result. There is no instance, in pathological science, which presents us with a more beautiful example of the curative effects of inflammation.

Surgery supplies us, in great numbers, with other cases, scarcely less admirable. It is under the guiding agency of these processes of inflammation, that collections of matter in the interior of the body, are brought safely to the surface, or some organ communicating with the external air. Abscess of the liver, bursting into the bronchi, colon, or surface;—the formation of an artificial anus, by the agglutination of the opposing layers of peritonæum, and their subsequent ulceration;—the adhesion of serous coverings of cavities, limiting the extension and quantity of effusion;—the spontaneous and artificial obliteration of the cyst of the tunica vaginalis in hydrocele, and of the cyst in ovarian dropsy;—may be enumerated as examples of the salutary effects of inflammation. The genius of Dupuytren recognised this principle, when he proposed his operation for artificial anus:—the suggestions of Dr. Marshall Hall, with respect to the surgical cure of *prolapsus uteri* (by causing adhesion of the sides of the vagina) and the obliteration of the vascular plexus, in *nævus*, by the frequent introduction of a needle, had immediate reference to the restorative power enjoyed by inflammation:—a knowledge of this principle likewise led Sir A. Cooper to the cure of varicocele, by removing a portion of the integument from the upper part of the cord—and thus by the formation of a binding citratrix, prevent the enlargement of the spermatic vein.—*T. Williams.*]

## SECTION I.—GENERAL DEFINITION.

The general definition of inflammation is,—“redness, swelling, heat, and pain;” that is to say, *morbid* heat,—*morbid* redness. Swelling and pain require no definition, but redness is healthy in some parts; and therefore we must understand “*morbid* redness;” and with respect to temperature, *morbid* heat. These are the four chief symptoms of inflammation,—those which make the definition in general. The words of Celsus are,—“*rubor et tumor, cum calore et dolore.*”<sup>a</sup>

These are the general constituents of inflammation; and if they do not all exist in all cases, still the greater number are usually present. Sometimes one is absent, sometimes another; but the *redness* is never absent. The redness is certainly indispensable to our idea of inflammation; and it will sometimes exist without swelling, without heat, or without pain; or with the absence of any two of them; and now and then the redness will exist alone. Whether the state should then be called “inflammation” or not, may give rise to a difference of opinion. Frequently, however, inflammation exists, without any perceptible swelling. We must conceive the part to be a little increased in size, because there is more blood than natural; but without a sufficient enlargement to justify us in using the word “*swelling*;” there may not be much increase of heat, and pain may be wanting; and it is to be remembered, that both the increase of temperature and the redness (by which we understand a *morbid degree* of them) may arise from other circumstances than inflammation; as may also the swelling and pain.

*Redness.*—Still, although redness is indispensable to inflammation, it is not every redness that we have a right to call “inflammation.” A certain degree of it is necessary to the idea of inflammation. How much, cannot be specified; but, like sensations in general, it must be experienced to be learned. The requisite intensity will vary in different parts, according to their natural colour. A blush, or moment-

<sup>a</sup> “Celsus de Medicina,” Lib. 3, Cap. 10.

ary rosiness, is not considered an inflammation; and every part is liable to this momentarily in health. As regards the cheeks, a degree of redness there would not be considered inflammation, which we should be fully justified in calling so, if it affected other parts of the body. The most intense redness, if it last only for a moment, we should not call "inflammation." In the cheeks it must be,—supposing the person has a natural colour,—a very deep red indeed, and more or less permanent,—at least not a *transient* redness, though *intense*,—to enable us to say that the cheeks are inflamed.

Again: the same degree of redness,—the same intensity of it, would not be considered inflammation if alone, which would be considered so if there were also pain and morbid sensibility. If we saw in the cheeks a great redness, we should not hesitate to call it "inflammation," if we found the part were morbidly sensible; or if the patient complained of its smarting, and being painful independently of pressure. Although the redness might be less intense, and might not continue so long as alone to justify us in calling it "inflammation," yet provided it were in a part which is not naturally red, like the cheeks,—not liable (like them) to occasional flushing and rosiness,—a much less degree of it, and much shorter continuance, might give us the idea of inflammation. Thus we see how many things are to be taken into account. A knowledge of these things cannot be gained at once; and many circumstances must be called in to aid us in our judgment. When persons are speaking of redness in connection with inflammation, instead of the mere expression "*redness*," we ought to say "*morbid*," or (perhaps) "*preternatural* redness;" because what is morbid redness in one part, is not morbid redness in another;—redness preternatural to the part affected.

[In the experiments of Hunter upon the ear of the rabbit, and the observations of Kaltenbrunner, redness appeared as one of the earliest consequences of an injurious impression upon the part. In the web of the frog's foot, it has been oftentimes observed, in an unequivocal manner, that an augmentation of colour is co-equal with the initial lesions, in the capillaries of the part undergoing inflammation. Nor is this, *à priori*, improbable;—as will afterwards be rendered obvious, when describing the microscopic changes in the affected capillaries. It will then be explained, that the *first* appreciable deviation from the ordinary condition of the part, consists in a diminution of the calibre of the minuter arteries, and capillaries. In obedience, therefore, to the recognised hydraulic law, the rapidity of the contained current will increase in a ratio directly as the contraction. But it will be readily conceived, that the augmented velocity of the current will not adequately compensate the straitened capacity of the channel. It is therefore concurrently remarked by different microscopists, that the *detained* blood, by its mechanical distension, and, according to Müller, its *vital* stimulation, excites the capillaries in the immediate vicinity of the *primarily* irritated vessels; and thus, quickly diffusing the original cause, induces a vigorous activity in the capillary circulation of the inflamed spot. This exalted action, then, unattended by any visible organic change,—distinguished only by a circumscribed acceleration of the circulating fluid, and a diffused blush of arterial redness,—specifically constitutes *irritation*. Without anticipating what, more appropriately, will come under another chapter, it may be observed, that this redness, for its character or shade, is dependent upon several circumstances. The *nature* of the affected part has considerable influence alike upon its intensity, and tint or shade. The quality and nature of the *causative* agent, however, exercises still greater influence over the *character* of the resultant inflammation.

With a view to determine, with greater exactitude, the extent to which different agents—externally applied, or ejected into the trunk of the vessel distributing its branches over the inflamed part—modified the *colour* and character of the consequent inflammation, I instituted a series of experiments, originally suggested by the researches of Majendie; in which he artificially induces fevers, of different types, by the introduction of septic poisons into the system. Decomposed matters of a vegetable kind, generate fevers of an *intermittent* character; while those of an animal nature, induced the *continued*-typhoid species,

In these investigations, I found that diluted muriatic acid, injected into the carotid artery of a rabbit, considerably exalted the circulation of the ear, and produced a *scarlet colour*. The red particles appeared contracted in size; and, therefore, a greater number pass through the capillary, than under the agency of ordinary stimuli. Common water produced an evident enlargement of the calibre of the vessels, a subdued and confused redness, with a visible alteration in the figure of the *particles* flowing through the part;—an appearance which finds a plausible explanation in the action of water upon the red particles only of the body;—carrying away, by rapid solution, the envelope of colouring material. Liquor potassæ produced a similar appearance under the microscope. Various fluids, in different stages of decomposition, were likewise introduced by means of a fine syringe; but in none of the cases were there distinguishable effects of a distinctive character. In all, the blush induced presented a dark colour, or one approaching brown. While they are acknowledged to be imperfect, these inquiries reflect important light upon the *varieties of colour* presented by inflammation, under varying conditions of the general system, and the quality of the blood, irrespective of the structure or organ in which it exists. Nor is the discrimination of *shade* presented by an inflamed part unimportant; since, in the treatment of disease, success will often paramously rest upon ascertaining whether an inflammation be simple or malignant, ordinary or specific. In surgery, it is quite orthodox to regard an inflammation discovering a blue, or purplish tint, as associated with the operation of some poison in the system. It is universally known, likewise, that these cutaneous and other inflammations, which depend upon the circulation of a syphilitic virus through the body, are marked, characteristically, by a coppery shade. These practical facts, then, interestingly teach the consequences which result from attention to the *character* of the redness, in different species of inflammations. It may here be noticed, as a physiological circumstance of interest, that Haes, and Wedemeyer, in experimenting upon the relative power of the arteries, and capillaries, observed, that when stimulating fluids were injected into the torrent of the circulation, they exerted their chief effects upon the capillaries; but themselves passed through the capillary vessels at a much slower rate than the blood;—demonstrating that some adapting vital affinity subsists between the blood and the living membranes of the vessels; thus rendering its onward movement rapid and free.—*T. Williams.*]

*Heat.*—We will now proceed to the consideration of the other symptoms; and first of *heat*. For the same reason which makes one adopt the epithet “*preternatural*” or “*morbid*,” with regard to redness, we should likewise affix the same epithet to heat; because the body,—in this country (at least), and in most others,—is hotter than the surrounding temperature; and therefore it is always hot. A preternatural heat, if not very great, is not of necessity inflammatory. A certain intensity, and a certain duration, are necessary to constitute inflammation in the case of heat, as well as in the case of redness. The greatest intensity of heat, if transient, would not be considered inflammation. The burning heat upon the cheeks, the palms of the hands, and the soles of the feet, in hectic, is never considered inflammation, even though it be combined with preternatural redness. The most intense heat, and also the most continued, is not of necessity inflammation, unless it be united with a permanent preternatural redness. The example of hectic shows, that even a combination of heat with intense redness is not sufficient to give the idea of inflammation; for in these intense spots in hectic there is no pain, nor are the parts most affected tender on pressure. In addition to the temporary duration of the morbid heat, there is no swelling in that affection; and therefore we have still greater reason for saying, that it is not inflammatory.

With regard to heat, the temperature of the affected part appears much higher to the patient, than it really is;—a circumstance which arises from the morbid sensibility of the parts. In palsy it is not very uncommon, when there is no increase of temperature,—no inflammation, for the patient to feel every thing hot; so that if he sit on any thing without his clothes, it causes a sensation of heat; or if he put

his hand on any substance, whatever it may be, it appears as if it were heated. This is a peculiar state of the system, which is not inflammation. There is in inflammation a general morbid sensibility of the part; and therefore the degree of heat which actually occurs, produces greater effects than it would in any other part of the body. But although, from the morbid sensibility of the part, the increase of heat appears greater than it really is, there can be no doubt that in inflammation the temperature is raised. When the nostrils are inflamed, or the bronchial<sup>a</sup> membrane, or the throat, the air that we expire is so heated in passing over the parts, that (as it comes out at the nostrils and lips) it is felt to be burning. If the hand be applied (in a state of perfect health) to the inflamed part it feels hotter than usual; and if the thermometer be used, the point is ascertained to a nicety. The parts inflamed appear hotter, by many degrees, than other parts of the body. It is not uncommon to find them at 107°. John Hunter made experiments, to show that the temperature of inflamed parts was but little augmented;—at least not higher, nor even so high, as that of the blood at the heart and in the chest;—that if the parts had naturally a lower temperature than the centre of circulation,—as for instance, the hands and the feet,—when they became inflamed, their temperature never rose so high as that of the centre of circulation. The general temperature is said to be 98°; but it varies in different parts. The farther removed from the heart, the lower it becomes; because there is less circulation there, and the parts are more exposed to the temperature of the surrounding atmosphere.

*John Hunter's Experiments.*—John Hunter produced inflammation in the thorax, peritonæum, rectum,<sup>b</sup> and vagina; and he found the heat but one degree and a half higher than before the inflammation; and he frequently found it unaltered. He states that the temperature of the vagina, at the utmost, increased to 101½°; but he found the temperature of the tunica vaginalis only 92° in health; whereas, when inflammation was produced in it, it rose to 99¾°;—98° being about the natural temperature of the body. It is to be remembered, however, that the scrotum is a part very much exposed to the surrounding air,—a depending part; and is therefore as much exposed to the atmosphere, as the hands, feet, ears, or nose. He infers, further, that the heat is never raised above the natural standard at the centre of circulation. If the natural temperature of the tunica vaginalis be 92°, certainly the increase to 98¾° is very considerable. He remarks, that he once found the abdominal fluid raised as high as 104°, and that if inflammation attack any part with a temperature of 98°, the heat may proceed beyond that of a healthy person. Now, however correct these experiments may be, it is only necessary in the case of erysipelas to take a thermometer, lay it upon the inflamed part, and cover it up. It will be seen that the temperature, although it be erysipelas of the leg, is often raised to 104, 105, 106, or 107 degrees.

*Everard Home's Experiments.*—That the temperature of the body may be increased very considerably, in various circumstances, is shown by the following facts. Sir. Everard Home<sup>c</sup> observed the oviducts of a frog when about to spawn, and when a great local activity of circulation was going on, to be two degrees higher than the temperature of the heart. There was no inflammation here; but merely a great activity of circulation, *approaching* to inflammation;—such as occurs in the generative process; and the result was as I have stated. If, then, a mere natural process, short of inflammation, will raise the heat above that of the centre of circulation, we may well suppose what inflammation will do. Even in vegetables, when a certain process is going on with great activity, a very considerable increase of temperature takes place. When the *arum cordifolium*, and the *arum maculatum*,

<sup>a</sup> From *βρυχος*, the throat.

<sup>b</sup> From "rectus," straight; owing to an incorrect notion of its course.

<sup>c</sup> It is only an act of literary justice to John Hunter, to caution the reader against receiving any thing which Sir E. Home has published, as his own;—since the exposure that recently took place before a parliamentary committee, has associated the memory of Home with eternal infamy,—as the foulest literary robber that ever disgraced the annals of science in this, or any other, country.—T. Williams.

are about to burst, the increase of temperature is such, that by placing a considerable number around a thermometer, the latter has been raised very considerably. Twelve were placed around a thermometer; when so high a degree of heat was developed, in the physiological process of bursting, that the instrument was raised from the temperature of  $70^{\circ}$  to that of  $143^{\circ}$ . Even in fever, by placing the thermometer under the tongue, we find the temperature raised many degrees; and the same occurrence takes place in acute rheumatism. In one case of phlegmasia dolens, on placing the thermometer on the thigh, and covering it with the hand or bed-clothes, I found it rise to the same degree of heat that is frequently observed in fever, and in acute rheumatism;—namely, to  $107^{\circ}$ . Indeed, one gentleman says that, having introduced a thermometer into the vagina, during labour, he has observed the temperature of the uterus to be  $120^{\circ}$ . During the violence of the spasm in tetanus, the temperature is frequently as high as  $107^{\circ}$ . There can be no doubt, therefore, that inflammation is frequently attended by a great increase of temperature.

But as increased heat may exist without inflammation, so inflammation—that is to say, redness and swelling, of an undoubted inflammatory character—may exist without any preternatural heat. Inflammation—that is to say, preternatural redness and swelling, going on to suppuration—may exist without any increase of heat;—a state which has been called “*passive inflammation*.” Some regard this condition as only one of congestion. But it will go on to suppuration; and therefore may be called “inflammation,” although there is no increase of heat. Discrepant notions have prevailed with regard to the limits within which the term “*inflammation*” should be restricted;—some supposing the presence of pain, others of heat and redness, necessary to constitute this state. Andral calls any state in which there is a morbid collection of blood, “*hyperemy*,”<sup>a</sup>—excessive quantity of blood in a part; when it is actively inflamed, “*active hyperemy*,” and when a passive state occurs, he terms it “*passive hyperemy*.” Thus he gets rid of the difficulty altogether, by no longer using the word “*inflammation*,” but by using a word signifying “congestion of blood,” and applying one epithet (“*active*”) or another (“*passive*”) to it.

*Swelling*.—If we consider the third of the symptoms (swelling), we shall find that it also may exist without any inflammation. Swelling, although frequently a symptom of inflammation,—more frequently than not,—may (just like an increase of temperature, or an increase of redness) exist without inflammation. Any injury produces a swelling. The mere displacement of a part (the dislocation of a bone, or hernia), the effusion of hæmorrhage, a collection of water, any morbid growth (whatever its character), or the presence of air within the body,—will produce swelling. For a swelling to be considered inflammatory, it must be united with pain or a preternatural redness; and even then it may be chiefly dependent on other causes. In dislocation, for instance, inflammation of the ligaments and integuments may occur,—producing pain; but the swelling arises chiefly from the displaced bone. Again: it is to be remembered that inflammation may sometimes exist without swelling; as is occasionally noticed in ophthalmia;<sup>b</sup> in which the turgescence often gives rise to no perceptible swelling. Frequently, however, this affection, and many superficial inflammations of the skin, are not attended by any swelling. A part will appear inflamed, sometimes without the presence of pain or increase of temperature; but marked by excessive redness and excessive swelling. The congestion is extreme; and gangrene, in such a case, is very likely to take place.

It is therefore evident, not only that the symptoms will arise from various other causes than inflammation, but that, when they do occur, they are frequently out of proportion to each other. Sometimes a little inflammation is attended by very violent pain; and sometimes a little inflammation,—a little increase of heat, is attended by a most violent swelling. There is no necessary proportion between any of these symptoms.

*Pain*.—The last of the marks of inflammation (pain), may arise from many

<sup>a</sup> From *υπερ*, in excess; and *αιμα*, blood.

<sup>b</sup> From *οφθαλμος*, the eye.

other causes than inflammation. Pain will arise from a mere spasm.<sup>a</sup> Nothing is more painful, for example, than cramp in the legs. Pain frequently arises from scirrhus, or cancer; which some call "chronic inflammation;" but certainly there is something superadded. Pain, too, is frequently neuralgic; being dependent on a violent affection of the nerves, in which no inflammation can be detected during life, and no effect of inflammation discovered after death. Pain continually arises from inflammation; but it continually arises, also, from the other sources just pointed out; and sometimes it is *absent* in inflammation. A part is violently red, and violently swollen, without any pain at all; and sometimes nothing is worse than this state; for the part may fall into gangrene.

*Characters of Pain.*—The character of the attendant pain varies with differences in the structure of the part in which it occurs. If the part be unyielding, then the pain is of a tense character and great in severity; hence inflammation of the theca of a tendon, is generally attended with great agony. From a similar cause, also, when matter is formed and cannot escape, the pain is most agonizing; whereas, on making an incision, so as to allow the escape of even the smallest quantity of matter, and so relieving the tension, the pain instantly disappears; and thus the great irritation of the system, which, perhaps, amounted to a violent delirium, also vanishes. Hence, too, the great use of incisions in certain inflammations of the skin and the cellular membrane; where the latter becomes excessively gorged with fluids, and the skin is distended over it,—producing the greatest agony; but a few incisions afford immediate relief. If it be inflammation inclining to suppuration, the pain is of a throbbing character. If the skin be affected, the pain frequently assumes a smarting or tingling character. If a mucous membrane be inflamed, there is frequently a burning and pricking pain; while inflammation of a serous membrane is characterized by a stabbing sensation,—as though a knife were being plunged into the part. The difference in the character of the pain in inflammation of serous and mucous membranes, is owing, I presume, to the fact, that serous membranes, in general, are tense, and therefore give rise to the most violent pain when inflamed; whereas mucous membranes are all of a more yielding character; and, consequently, inflammation of them is never attended by this violent stabbing pain.

Sometimes there is merely a soreness;—no pain is felt unless the part be irritated mechanically, or some particular stimuli are applied. Again: parts which have little or no sensibility in health, acquire a degree of sensibility, under inflammation, which is frequently very intense. Many parts that may be cut in health, without the individual experiencing any sensation, cannot, when inflamed, bear the slightest motion or pressure. If, therefore, parts which show no sensibility in health, become very sensible in inflammation, we may fairly suppose that parts which are naturally sensible in health, may become very painful when in a state of inflammation.

*Pain affected by Pressure.*—The pain of inflammation is generally increased by pressure,—at least by *sudden* pressure; while pain arising from spasm is generally *relieved* by pressure. This is very strikingly shown in colic and enteritis. In the latter, the pain proceeds from inflammation, and is aggravated by the slightest pressure; while, in the former, which is spasmodic only, pressure rather diminishes than augments the pain. It is necessary to remark, however, that although the pain of inflammation is increased by pressure, it is rather due to its sudden or partial application. For, if pressure be applied suddenly to an inflamed part, or if it be only applied to a part of the inflamed surface, then the capillaries cannot be emptied with sufficient rapidity, and pain results from the degree of tension which is produced. If, however, the pressure be applied slowly, or over the whole surface,—so as gradually to empty the capillaries, or diminish their contents,—then little or no tension is produced; and, consequently, pain is either absent or very trifling.

*Pressure, a Curative Agent.*—Pressure, therefore, has been recommended as a

<sup>a</sup> From *σπασ*, to draw.

means of cure, by certain writers, in some inflammatory diseases. It was advocated, for the cure of gout and rheumatism, by Dr. Balfour, of Edinburgh; and by Velpeau, in erysipelas. But it frequently happens that, although relief may be given in some cases, considerable aggravation is excited in others. It is necessary that the part should be equally compressed; for any deviation in this respect, by which a part of the vessels might become more distended, would only increase the mischief. Very frequently, too, inflammation does not depend altogether upon local causes. There is a tendency to it in the constitution. The circulation of the part, although impeded, suffers little diminution in its impetus; the large arteries around are found to throb violently against the part compressed; and pressure frequently cannot be borne at all. On all these accounts, it is exceedingly difficult to cure inflammation by pressure. As a general rule, however, we may say that the pain of spasm is *diminished* by pressure, and the pain of inflammation *increased* by it; and this criterion is continually resorted to, as a means of diagnosis;—as a means of distinguishing whether pain be inflammatory or spasmodic.

Inflammation is generally known by pain, increased on pressure; by feverishness; and by a disturbance of the function of the part. When a person is observed labouring under disordered function, under feverishness (pyrexia), and under pain increased by pressure, a strong presumption is afforded, that the proximate cause of these symptoms is inflammation. Sometimes there is no pain experienced, but simply disturbance of function and feverishness; and when such is the case, the presence of internal inflammation may be questioned. When a part can be seen, the symptoms which I have already mentioned (pain, heat, redness and swelling,)—few or more of them,—will be sufficient to characterize the complaint; but we are certain also of the existence of inflammation, even when the part is invisible,—when we cannot ascertain whether it is red, hot, or swollen, or not; but where there is pain increased on pressure, the function of the part is disturbed, and the patient labours under what is called “feverishness,” or “pyrexia.”

## SECTION II.—APPEARANCES AFTER DEATH.

The foregoing are the symptoms of inflammation during life; but they may have existed at that period, and yet none of them remain after death. The pain and the heat, of course, must disappear; but the redness and swelling might be expected to remain. When, however, the part inflamed during life is seen, or such symptoms have been present as to leave no doubt of the existence of inflammation, in both cases it may be found, on examination after death, that no marks of inflammation are discoverable. Yet the absence of these marks does not, in any way, invalidate the opinion formed during life; for it will sometimes happen that, after death, every mark of inflammation will disappear. In inflammation of the surface of the body, or the eyes, visible enough during life, we find both parts pale after death. The skin, perhaps, will be slightly swelled; but the swelling will be greatly diminished, and the redness entirely gone. After apoplexy, frequently nothing is observed; although, during life, the head appears to be bursting from an accumulation of blood, and the patient dies of the complaint, yet, after death, no morbid appearances can be discovered.

[There are many observations made by Dr. Carswell, in his “Elements of Morbid Anatomy,” which render it probable that all variations of appearances presented *post-mortem*, by parts which were, *ante-mortem*, unequivocally inflamed, are referable to two circumstances;—that of position, and that relating to the extent or grade of inflammation before death. Although Dr. Carswell does not carry the explanation further, I think it may with probability be suggested, that if any disorganization has occurred, even to the extent of causing a stagnation and coagulation of the blood in the inflamed part, and therefore the adhesion of its red particles and fibrin to the sides of the vessel, no disappearance after death can occur. It is evident, however, that at any limit short of this extent,—as in congestion and irri-

tation only,—a more or less complete disappearance of the blush may take place, when the operation of the exciting causes ceases, by the occurrence of death. This explanation is further supported by the valuable practical views of Dr. Carswell. He states it as a circumstance, the truth of which is established by his extensive pathological researches, that the *permanence* of the redness, and vascularity of inflammation after death, is the only character, under doubtful circumstances, by which its existence can be determined, and its distinction from other local congestions with which it may be confounded, conclusively made out.—*T. Williams.*]

*Redness.*—On the other hand, it is not every preternatural redness, discovered after death, that is inflammatory. It is not unusual to find an intense redness of the internal parts in the bodies of patients, who did not, during life, present any symptoms of inflammation; and such an appearance is not enough to justify belief in its previous existence; for, just as the redness of inflammation will frequently disappear after death, so, after death without any antecedent inflammation, morbid redness of the parts may occur. If the patient have died with great difficulty of breathing, a large accumulation of blood has taken place in the lungs; and the liver may be found gorged with blood, and the mucous membrane of the stomach and intestines exceedingly red;—not from inflammation; but simply because the blood was obstructed in the lungs, or in the heart; and from the consequent occurrence of congestion. In a case of great debility, a continuance of the patient in one posture during the latter period of his existence, will cause such an accumulation of blood as, after death, to give rise to great redness; and these appearances are always greater, in proportion to the number of capillary vessels in the part to which the blood inclines by its gravitation. The blood will not merely accumulate in the vessels, but will transude from them, and dye the surrounding parts perfectly red, and prevent the distinction of the appearance from inflammation. This is particularly the case in hot climates and in hot weather. Dr. Davy, the brother of Sir Humphry, says (in a paper published in the tenth volume of the “*Medico-Chirurgical Transactions*”), that in hot countries he has often found it impossible to distinguish the redness of inflammation, from the redness of transudation, or from the redness acquired by a piece of membrane merely steeped in blood; and from all his observations and experiments he draws the conclusion, that if, in a hot climate, a body be not opened within twenty-four hours after death, the surfaces become red; that the serum of the cavities likewise becomes bloody, and that the viscera become livid; so that no opinion can be formed as to what was the state of the parts during life. The reason is this;—the hotter the temperature (within certain limits), the sooner does decomposition take place; and the more a part is decomposed, of course the more easily does transudation occur. The solids become more soft,—more spongy; and blood which comes in contact with them, easily pervades them, oozes through them, and dyes them, and any of the liquids which the parts may happen to contain.

*Redness simulated by Transudation.*—In dead bodies which have lain any time upon their back, especially in hot weather, the posterior parts all become livid, and filled with blood; while the anterior parts become pale. The body being usually placed on the back, the lungs, towards the posterior part, are heavy,—filled with blood,—livid; and, in fact, exhibit the same appearance as the anterior part does in violent bronchitis; and every one accustomed to make post-mortem examinations, allows for this occurrence. He never thinks of considering it a morbid appearance; it is simply the effect of the blood gravitating to the lowest parts. It is observed, also, when bodies are at all decomposed, that red streaks appear along the surface, in the direction of the various veins. As, after death, the blood accumulates in all the veins, and as the substance of their coats becomes more and more decomposed, the blood contained within the veins transudes; and thus the coats themselves become thoroughly dyed with blood, and the cellular membrane likewise around the vessels. The superficial veins may be traced in the dead body from this appearance. This is nothing more than a transudation of decomposed blood.

The observations made by Dr. Davy, many years ago,—respecting the importance of examining bodies early in hot weather, and showing the importance of knowing that such appearances as are induced by inflammation may take place merely from decomposition,—have been all lately confirmed by Andral; who, to make his observations the more striking, has examined the same part of the body at different periods. Early after death, he has found an organ pale; but if it were afterwards so placed as to favour the gravitation of the blood to a certain portion of it, that part of the organ, when examined in a few days,—decomposition having proceeded,—had become intensely red.

The blood will not only accumulate in the solids in this manner, and not only exude in sufficient quantity to dye any liquids that may be within the cavities, but it will itself exude to such an extent, that a canal may be found containing a large amount of pure blood. By causing a considerable portion of intestine to be dependent, the blood has gravitated to such an extent, as to pass through the vessel into the cavity, and lie there in the form of a hæmorrhage. Two French writers (Rigot and Trouseau) have made numerous experiments upon this subject; and they say that they have frequently made the blood ooze from the inner surface of the intestines, by merely giving a portion of them this dependent position.

*Effects of Time, Gravitation, and Obstruction.*—The mere appearance of redness, therefore, is not sufficient to justify us in saying that a part has been inflamed. A part may be red because it was inflamed during life; but we must always take into consideration whether the body has lain long;—so as to be partly decomposed, and to allow the diffusion of blood into the substance of the parts. Indeed, not merely does a degree of putrefaction allow this infiltration of blood into the parts, but the parts themselves become dissolved into a liquid substance;—they liquefy. As the body putrefies, it becomes soft; and a large quantity of liquid is produced, in addition to the pure blood; and assists materially in dyeing the different parts. We have therefore to take into consideration what is the period at which to examine the body, and also the position of the part;—whether it be such as to have favoured the gravitation of its own blood, and that of other parts, in any quantity. We have also to take into consideration another circumstance, independent of time and of position;—that is, whether any mechanical obstruction existed during life. If there have been a mechanical obstruction to the return of the blood through the lungs and heart, the redness of the stomach will be explained, without the necessity of referring it to inflammation. There are, therefore, three circumstances to be taken into account;—the period at which the body is examined, the situation of the part as to gravitation, and the previous existence or non-existence of mechanical obstruction. A simple inspection of the parts which are red (provided there is nothing but redness), will give no information whatever; unless the symptoms during life have been ascertained, and the three circumstances to which I have just alluded observed.

*Effusion.*—There is, however, another circumstance, which will frequently enable us to say that inflammation actually existed;—I mean the presence of the products of inflammation. If the part be intensely red, and a layer of lymph effused, or a large quantity of serum,—perhaps *turbid* serum,—with flakes,—the redness may be regarded as inflammatory. The redness, it is true, may be increased by decomposition or by mechanical circumstances; but if the products of inflammation are observed, it may be concluded that the redness, in great part, is inflammatory. These observations are useful with respect to inflammation in the inner surface of the heart. The lining membrane of the cavity of the heart, especially at the valves, is sometimes very red, without any inflammation. Some persons will say there was inflammation during life; others will say there was not. Of course the point may generally be cleared up by minute observation;—by feeling whether or not the heart is soft, so as to allow the membrane to be stained by transuded blood; but if an effusion of lymph upon the membrane is seen, it is certain that the redness is of an inflammatory character;—that it is the result of inflammation, either in part or altogether.

These are the observations which I have thought it necessary to make respecting the marks of inflammation during life and after death.

[Besides the redness of the part, and the presence of the products above mentioned, its texture should also be noted as an element which may assist us in determining whether a tissue or organ has or has not been the seat of inflammation. Acute inflammation almost always gives rise to softening. Thus the lung in the second stage of Pnenmonia, although more dense and thus apparently firmer than natural, is in reality less coherent, so that the finger will penetrate it with the slightest force. Mucous membranes are generally both thickened and softened, under the influence of acute inflammation. Softening, however, may result from other causes, as perverted nutrition and cadaveric changes; hence it is not alone proof of inflammation. Like the other evidences mentioned, it is only valuable when viewed in connection with these, or with other circumstances. Induration is rarely met with except where inflammation is chronic, and is most commonly a termination of it. T. S.]

### SECTION III.—PATHOLOGY OF INFLAMMATION.

Having described the various signs by which the presence of inflammation is indicated during life, and after death, let us, in the next place, examine what are the pathological conditions necessary to the production of these effects.

*General Remarks.*—That blood-vessels have a contractile power in the large vessels is well established; the capillaries likewise have been proved by Schwann to possess the same power. The action of the capillaries, and arteries, *contribute* to the circulation in health; and in disease they *alter* the circulation, according as they are constricted or dilated;—thus supplying more or less blood to the part itself, and those parts to which these vessels lead. But although it is quite certain that the arteries and capillaries have this power of contraction, and although I doubt whether it can assist in *furthering* the circulation, (though it certainly may, and certainly does *alter* it every day,) I cannot conceive that this increased action is compatible with increased redness and fulness. I cannot conceive that, in inflammation, when a part is redder and fuller than it should be, there can be increased action;—by which I mean, that the vessels can be at once more constricted and more dilated, than before; for if they were redder at the one moment, they would be paler at the other;—the one state would counterbalance the other. But whether there be increased action or not, it appears certain, that there is a diminished motion of the blood, in inflamed vessels; this retardation is commensurate with the inflammation. This has been shown by Vacca, Lubbock, Bichat, Allen, Dr. Wilson Philip, and recently, under the microscope, by Dr. Hastings. Still more recently, Gendrin has confirmed the observations which were made by Drs. Philip, Hastings, and others. They applied mechanical violence, heat, cold, and ammonia; and they perceived, by the microscope, that at first the blood moved more rapidly. There was an increased velocity; and a contraction of the vessels was seen, inducing paleness. After the increased action,—after the contraction of the vessels, the motion became slower; the course of the blood was retarded; the vessels became dilated; and inflammation appeared. In this they all agreed. If the part was already inflamed, the application of a stimulus had the immediate effect of quickening the blood's motion, and constricting the vessels; and then the inflammation ceased. If the stimulus were applied very violently, so as to produce most violent action, and extreme rapidity, of course this lasted a shorter time; and the second stage,—that of slow motion, dilatation of the vessels, and inflammation,—came on sooner. By applying the stimulus very violently, the second stage might be made to come on immediately. It would appear from these experimenters,—who are very numerous, reside in different countries, have succeeded each other, and have each repeated the experiments with a view to ascertain whether his predecessors were correct or not,—that, in an inflamed part, the blood moves more slowly; that the vessels

are dilated; and that, by applying stimuli, you cause the vessels to contract, and the blood to move more rapidly; and that then the inflammation ceases for a time, till the blood is retarded again, and the vessels dilate. One would not expect that cold would have exactly the same effect as stimuli; but such was found to be the case. We all know that, if parts are cold, they become reddish; as is seen in the nose and cheeks in winter. They grow dark,—more and more red; till at last they become of a mulberry-colour; and congestion sometimes takes place to such an extent, that gangrene occurs.

The large vessels going to an inflamed part, are frequently felt to throb. If there be a whitlow upon the finger, the digital artery behind it throbs violently; and, in inflammation of the face, the angular artery may be felt doing the same. In the case of headache, the temporal artery is in a similar condition. This, however, is no proof of increased action in these vessels; for the same occurs in an aneurism, or a dilated artery. When an artery is dilated (though weakened), softened, and unable to act as it did before, it will be found to throb violently. In that kind of inflammation which is called *passive*, and which some say is not real inflammation, but mere congestion, this enlargement of the surrounding vessels is wanting; so that there is no throbbing of the large vessels. When a mucous membrane is inflamed, its secretion will stop. The secretions of a part, at the height of inflammation, cease, or at least are greatly diminished; so that a spasmodic and constricted state must be supposed to exist; though, perhaps, the word "*spasmodic*" may be objectionable. Far more changes than these, however, take place. The blood is buffed and cupped; it contains more fibrin; and this fibrin is thinner than it ought to be. The blood, in the small vessels, becomes homogeneous,—broken down; the red particles are indistinct; and sometimes flocculi are seen in it, which are not visible in the immediate surrounding capillaries. When a part is mortified, the blood around it is yellow; its various constituents separate; and it is evidently in a state of disease.

With respect to the symptoms of inflammation, the *redness* is very easily explained, from the existence of blood in vessels that ought not to contain it, and the existence of too much in those which *should* contain it. The *swelling* will arise from the same circumstance; and also from the increased secretion that is going on around. The *pain* will arise from fulness, and from the tension of all the parts. This is produced by the accumulation of blood; and by the excessive secretion around. But the pain will also arise, probably, from an increased degree of sensibility. There is, in every case, pain from fulness and tension; but the pain is felt far more severely, on account of the morbid sensibility. With respect to the *heat*, I presume it arises from the increased momentum of blood in the part;—the increased quantity which is circulating there. If the same quantity of blood were in the part, and motionless, of course the part would grow cold; but as the blood which is in it is far greater than usual, and still moves on so as to come round to the lungs, a greater number of changes giving rise to heat must take place. There is far more blood in the part than there should be; and as heat appears to be connected with the existence of blood which is circulating,—coming round to the lungs and undergoing chemical changes,—in proportion to the quantity of blood circulating, there must be increased temperature. If the blood ceases to circulate, or the circulation becomes languid,—so that it does not undergo a regular chemical change, then of course the part becomes cold. Momentum is composed of rapidity, and quantity. The rapidity is lessened, but the quantity is greatly increased; so that, on the whole, the momentum is greatly augmented.

#### a. Microscopic Condition of the Capillaries.

*Wilson Philip's Researches.*—[It is to Wilson Philip that we are indebted for the introduction of the novel method of investigating the ultimate lesions induced by inflammation, through the assistance of the microscope. The main conclusion which he deduced from his numerous observations, instituted so far back as the

year 1801, is—that the primary step consists in an enlargement and debility of the capillaries of the inflamed part, while the larger vessels leading to the spot are oppositely affected; having their currents appreciably accelerated, and their pulsations increased in power;—observing, further, that the blood in the enfeebled capillaries became retarded, and eventually arrested in its course; and that, subsequently, the same condition extended to the neighbouring vessels.

At a later period (1809) similar researches were prosecuted by Thomson; and afforded results analogous to those of Philip:—differing from them only in the point which related to the arrest of the blood;—the latter arguing that the blood suffers only a retardation in its flow through the affected vessels. It will be readily remarked, that these experimental observations, while we concede to their authors great ingenuity, place us little in advance of the knowledge brought down to us by the theory of obstructed vessels propounded by Boerhaave; or the hypothesis which supposed the existence of a spasm of the extreme vessels, promulgated by Cullen; or the profounder surmises of Hunter, in reference to the influence of vital endowments on the parts undergoing inflammation. More recent observers, however, have made important additions to our knowledge, in reference to the state of the capillaries under the operation of different substances, and the intimate changes in which inflammation consists. The experiment of Hastings, Kaltenbrunner, Wedemeyer, Koch, Oesterreicher, and others, have led to conclusions which enable us to entertain some definite views, in respect to the pathology and therapeutics of inflammation.

*Contraction and Dilatation of the Capillaries.*—According to the inferences authorized by their experiments, the changes which follow the application of chemical and mechanical agents to the small capillary arteries and veins, may be classed under two orders; *dilatation*, namely, and *contraction*. It is right to remark, however, that in different hands the same agents produced different effects;—common salt, ammonia, alcohol, hot water, ice, opium, acids, and mechanical injuries, (on different occasions, but apparently under similar circumstances,) causing opposite results with respect to the state of the capillaries.

*Contraction.*—From the constancy of its occurrence, the fact has at length been generalized into a law;—that the *contraction* of the capillaries is attended by an acceleration of the contained current, while their *dilatation* is accompanied by a retardation. Although the blood, *cæteris paribus*, must, according to the recognised mechanical law, flow more rapidly in a contracted vessel, it is obvious, that if its fluidity has been diminished, or incipient coagulation induced by the agency of the substance applied, its velocity will be considerably retarded. On the other hand, in a *dilated* vessel, the circulation, *cæteris paribus*, must be slower: *increased rapidity* of the current, in such a state of the capillaries, can be accounted for only on the supposition, that dilatation from an external cause may diminish the friction between the parietes of the vessels and the molecules of the blood (*Müller*).—Whether these two states, of diminished and increased diameter of the vessels, be explicable on mere chemical principles, or whether they are more properly referable to the subtle influence of vitality, would be rendering the subject too abstract to inquire. But we may, with Hastings, conclude, that the alcohol employed in these experiments, in virtue of its affinity for it, abstracts the water from the cells of the tissue in immediate contact with the cylinder of the vessel: and thus, by removing the distending agent, allows the collapse of each cell by its elasticity, and consequent pressure upon the capillaries;—hence their contraction.

*Turgescence with Dilatation.*—The opposite state of turgescence with dilatation, has offered a more difficult problem for the acumen of microscopists to explain. It is conjectured, by Müller, that, under the excitement created by a stimulus,—the innervation of the part becoming more energetic, the organic affinity between the blood and the coats of the vessel and the circumjacent tissue, acquires additional force; so that the blood is detained in the part, and thus gives rise to accumulation. Another and not less plausible explanation is given by M. Poiseuille.<sup>a</sup> He regards

<sup>a</sup> Ansell's Lectures on the Blood.—"Lancet" for 1839 and 1840.

the passage inwards into the vessel, of the fluid contents of the neighbouring cells,—caused by some peculiarity in the action of the agent,—as the manner in which *dilatation* takes place. It is not improbable that dilatation, when caused by the application of salt, is dependent upon endosmose alone (*Müller*). The salt, when applied to the part, penetrates the tissue, until it reaches the capillary vessels; an attraction is then exerted between the salt and the blood, which has a tendency to dissolve the salt, as the salt itself has a tendency to be dissolved in the blood; in consequence of this affinity, the blood will be arrested and accumulated in the capillaries; which subsequently become distended, and the circulation within them retarded. Majendie has carried further the attempt to make out a *rationale* for the action of these causes of inflammation; premising the discovery of a subtle fluid interposed between the innermost and middle tunic of the capillary, he labours to account for the phenomena resulting from the agency of these causes, by supposing that this attenuated stratum, like his sub-arachnoidean serosity, is absorbed and removed by the cause or substance applied. And, since the presence of this fluid is essential (by *lubricating* the internal tunic,—thus diminishing the friction between the revolving molecule and itself) to the integrity of the circulation, it may be supposed that its removal will be followed by the adhesion of the particles to the sides of the vessels; and a *dilatation* of their capacity will necessarily result.

It will perhaps be a speculation of too theoretical a character, to inquire into the relative merits of these several hypotheses. It has, notwithstanding, been thought desirable to supply the reader with a summary sketch of them;—as calculated to facilitate the study of the microscopic changes in inflammation. It may have been gathered, from the observations formerly advanced, that, according to the most recent and approved views respecting the ultimate character of these changes, whatever may be the nature of the agent employed to produce them, they pass with rapidity, varying with the circumstances, through three stages,—in theory intelligible, and in practice of the greatest conceivable importance. These stages are *irritation*, *congestion*, and *inflammation*.

#### *b. Pathological Changes in the state of the Capillaries.*

*Irritation.*—To pursue our investigation, in the order in which these stages occur in the living body, it will be required to understand, first, what is *pathologically* signified by the term “*irritation*.” I am the rather inclined to admit the probability of the explanations offered by Müller, Majendie, and Poiseuille, in reference to the mode in which contraction of the vessels (by the substances formerly enumerated) is occasioned; since the experiments of Treviranus, Wilson Philip, Baumgaertner, and Müller, have done nothing towards establishing the influence of the nerves over minute vessels and capillaries. It is most likely then that salt, alcohol, galvanism, mechanical injury, acids, and so on, when they *do* produce a state of contraction in the capillaries, operate chemically,—by abstracting the water from the adjacent tissues, or vitally,—by increasing the contractility of the investing tissue. Whatever be the *rationale*, it is now generally allowed, by minute observers, that the state which is distinguished by contraction of the capillaries, and an accelerated circulation, constitutes *irritation*,—properly so called. In irritation, then, there is no slackening or arrest of the current of blood; but an opposite state of augmented velocity;—in obedience to a common law in hydraulics, of which the expression is—that the rapidity is inversely as the area of the tube. Upon reasoning still more closely into the consequences flowing from this condition of the capillaries, it will appear plain that the increase in the momentum of the current will not adequately make up for the contraction. It is accordingly observed, that the detained blood finds its way into the neighbouring vessels, and induces a similar state of circulation in them; until, at length, the whole circulation of the part acquires such vigour and activity, as to give to the spot an erythematous blush; this state, generally, is one of temporary duration only; but the period over which it persists, will depend upon the nature of the cause, the quality of the blood, and

other circumstances; and likewise the quickness with which the second stage (*congestion*) supervenes. As this is not the place to continue the subject of *irritation* to its practical bearings, we shall proceed to the consideration of the succeeding change.

*Congestion*.—It has before been intimated, that the microscope discovers two things to be present in congestion;—namely, dilatation of the vessel, and an obviously retarded circulation, without any detectable stagnation; although, frequently, something very nearly approaching to it is observed;—the amount of motion in the blood being so small, that it resembles more a semi-revolving or oscillatory movement of the globules, than an actually advancing stream. During this stage, the characteristic marks of inflammation are not perceived. It is unnecessary to re-argue the mode in which the causes and agents capable of producing this intermediate state operates. It may suffice to state that, whether it be by the endosmotic entrance of the salt, alcohol, and other materials, into the interior of the vessel,—causing a disturbance of the affinities, which may be supposed to exist between the several constituents of the blood, or whether it be simply by mechanically distending the vessel, which is the least probable, the *ultimate* effect is dilatation.

*Inflammation*.—Provided the same causes continue to operate, and other circumstances be favourable, this state of turgescence will be replaced by that of *inflammation*. The initial step towards the production of this, consists in the coalescing of a few of the globules of the blood, and the adherence of them to the side of the capillary. A change also appears to occur in the *quality* of the blood; for the particles thus aggregated, no longer present their ordinary figure. The circulation, at the central point of irritation, is now completely suspended; and, for some distance round, the retardation of the blood, and dilatation of the capillaries, become very evident,—producing *congestion*. A little further from the focal point of action, the circulation is more active; the *still* dilated vessels, and the globules of blood, become less distinct; at least, at the extreme limits of the areola, the circulation is accelerated, the capillaries are *contracted*, and the blood abounds in arterial molecules,—constituting a state of *irritation*. All these transitions may take place in a few minutes. There are other phenomena, superinduced upon this state, which are of the greatest physiological interest. From the change occurring under these conditions in the constitution of the blood, and the new affinities between the blood and the tissues which are brought into play, the colouring matter falls away from the red particles;\* and the *liquor sanguinis* exudes from the capillaries,—the blood containing it in much larger quantity than under circumstances of health (as ascertained by Müller). The tendency to coagulation in this fluid, appears to be great in proportion to the quantity of fibrin contained in it; under intense action it solidifies quickly; it is a gelatinous fluid,—the invariable product of inflammation, modified, of course, in its quality by constitutional and other circumstances; it may either undergo organization, or rapid conversion into pus. When the former occurs, the red particles are *divested* of their coloured envelope; transude through the coats of the capillaries, by some mysterious vital process; re-acquire their red coats; and shoot, in various directions, through the effused fluid. Kaltenbrunner declares, that he has observed the red particles escaping from the interior of the vessel, and making arborescent tracts for themselves in the surrounding textures. This theory has always appeared to me improbable, on physiological principles; since the particles, thus extra-vascular, must immediately have their vitality extinguished. Nor are we to disregard the high authority of Müller upon this question. And without violating the rigorous laws of induction, we may argue in reference to the escape of the red particles, as he does with respect to pus globules;—that as hitherto all physiological investigations are opposed to the theory which admits the existence of pores in the walls of the capillaries, and, further, as the size of the red globule equals—that of pus exceeding—the diameter of the minute ves-

\* Gendrin.

sels, there is no warrant for the inference, that the red particles escape as such from the inflamed capillary. That hypothesis is less objectionable, according to which the globules are considerably reduced in size before their escape from the vessel; and afterwards, by an action going on in the effused fluid, are restored to their former figure. Whichever theory we adopt, however, to account for the formation of new vessels in the inflammatory product, it is very certain that they take place. Gruithuisen, who was the first to make any decisive observations upon this subject, inclined to the opinion of Gendrin;—that globules appear as red points, throughout the mass;—gradually enlarging, and soon presenting a stellated appearance. Hastings, likewise, seems to regard this as the mode in which the liquor sanguinis becomes organized. And, lastly, it may be observed, that Sir A. Carlisle<sup>a</sup> attempted recently to prove that vascular organization, at its commencement at least, is dependent more upon physical, than vital laws;—that the red blood, generated on the surface of the plastic matter extravasated in inflammation, radiates irregularly in the direction in which it finds least resistance—by mere mechanical force;—presenting, as the vessels become completed, a dendritic form. This hypothesis, however, is wholly untenable on physiological principle; since these changes must appear to all, to fall within the influence of the “creative power,” or “organic force,” so beautifully shown, by the masterly arguments of Müller, to regulate the building-up of all living matter. Although, in inflammation of a limb, the capillaries are extensively obstructed, it is known that the absolute quantity of blood passing through the arterial trunk and returning by the viens, is augmented in a ratio corresponding with the intensity of inflammation in the limb. Notwithstanding the plausibility with which these microscopic observations appear to explain the pathology of inflammation, there are many data presented in its progress which oblige the inference on our part, that an explanation on mechanical principles alone, is insufficient to embrace all. The act of resolution alone, by which the coalesced particles become disunited, and made again to circulate onwards, the capillaries resuming their former size and function, teaches that some creative organic force—wholly apart from mechanical laws—must, here, be in full operation.—*T. Williams.*]

#### SECTION IV.—COURSE OF COMMON INFLAMMATION.

Inflammation is usually divided into two kinds;—the one “common,” the other “specific.” “Common” inflammation is that which we see every day, where a local injury takes place, or when a part has been exposed to the vicissitudes of temperature; but the epithet “specific” is given to inflammation, when it runs a peculiar course; or when it arises from a peculiar cause, neither mechanical nor simply irritative. When inflammation runs a peculiar course, it is then by many called “specific;” but more frequently it receives that appellation only when it arises from a peculiar cause. For example: inflammation of the urethra, from the forcible introduction of a bougie, or of a catheter, would be “common inflammation;” but the inflammation of gonorrhœa, arising from a peculiar cause, is termed “specific inflammation. In *specific* inflammation, all the symptoms which occur in *common* inflammation are present; but some peculiarity is superadded.

*Common Inflammation.*—I will first describe the course of common inflammation. It may begin with pain, with a blush, and with a feeling of unusual warmth; but the redness is sometimes not in the form of a blush, but occurs in one particular point; from which it spreads. If the part be a secreting organ, its secretion will become changed in its appearance, and perhaps likewise in its odour, at the same time increasing in quantity. The pain and the redness increase in degree, and also in extent; and are succeeded by swelling, or tension, or both. The parts swell to a certain point; and if they cannot swell farther without difficulty, they

<sup>a</sup> Guy's Hospital Reports; April, 1840.

become tense. As the inflammation proceeds, the secretion of the part generally diminishes again; though perhaps it does not come down to, or does not descend below, its natural amount; but the secretions still remain unhealthy in appearance, and perhaps also in smell; the constitution subsequently suffers;—the pulse becomes quickened, and it likewise becomes variously altered in its volume, firmness, strength, and regularity. The affection of the pulse is not always according to the danger; for in mere inflammation of the tonsils, or in mere rheumatism of the joints,—both of which are unattended by danger,—the pulse may be rapid and violent. The same remark may be made with regard to the temperature. The temperature of the whole body will sometimes be greatly elevated, although the inflammation may be one of no danger. In a case of mere acute lumbago, I found the pulse at 160, and the heat of the whole body 107°. I find, in a note which I made, that the patient required no blood-letting at all;—that he merely took “vinum colchici” for three or four days, and yet his pulse was 160; and—by the thermometer placed in various parts of the body, under the tongue, and in the axilla—the temperature was found to be not less than 107°. The heat frequently varies, too, in different parts of the body.

Besides the alteration of the pulse and the temperature, the patient becomes restless,—uneasy in any position; and complains of general soreness. The whole surface of the body frequently becomes tender; the head and loins frequently become painful; and sometimes the pain in these two parts is among the severest constitutional symptoms. The derangement of the system extends to the secretions, so that most of them become diminished and altered; and from this circumstance thirst originally happens. The tongue becomes dry or white; and sometimes, if there be much gastric disturbance, assumes a yellow character; and if there be little strength, dark. The skin becomes dry; though, in one particular inflammation,—active rheumatism,—it generally falls into profuse sweating. The urine becomes scanty; and though it remains clear, it is high coloured, and has a strong animal smell,—resembling gravy-soup. The bowels become torpid, and the fæces unhealthy, both in colour and smell. These are all instances of diminished or altered secretion.

*Fever.*—These constitutional symptoms altogether, are called by Cullen and his followers “pyrexia.” We have no English word for this term, “*pyrexia*,” unless we use “*feverishness*,” but “*ish*” implies only a slight degree of any thing, whereas the pyrexia may be very great; and therefore the term “*pyrexia*” is always better. The word is used by Cullen to distinguish this constitutional excitement, in all circumstances, from those specific diseases, which (whether remittent, intermittent, or continued) he calls “fever;”—to distinguish it from fever properly so called. Some persons denominate these symptoms “fever” in all circumstances. Others, however,—aware of the confusion which might arise from calling these symptoms “fever,” and other specific fevers (such as typhus) “fever” also,—denominate these symptoms, when they are dependent upon inflammation, or some other local cause,—“*symptomatic*,” and they call the others,—fevers properly so termed,—“*idiopathic* fevers.”<sup>a</sup> These symptoms, which are, by some writers, called “constitutional excitement,” or “constitutional derangement,” are, by others, called “symptomatic fever;”—to distinguish them from real specific fever, which they call “idiopathic.” Cullen, however, does not employ the word “*fever*,” given to this state; but the word “*pyrexia*.” For the purposes of clearness, it can make no difference whether, in the case of inflammation, we say “pyrexia” or “symptomatic fever;” for the object of language is to render our meaning intelligible.

It very frequently happens, that when the local disease first begins,—before it has increased to such an amount as to quicken the pulse, and induce the other symptoms which I have mentioned,—the person complains of chilliness, a general soreness, and even rigors; so that he shivers with cold;—the pulse at this time

<sup>a</sup> From *idios*, peculiar; and *παθος*, an affection.

being small, the face pale, and the skin rough. From its deprivation of blood, and its low temperature, it is rough, and is called "goose's skin" ("cutis anserina"); and this state altogether is called "horripilatio." After the existence of these symptoms,—this cold stage, for a certain time, the inflammation appears, and the excitement of the whole constitution gradually comes on. Sometimes, therefore, inflammation begins; and, after a certain period, is attended with constitutional excitement; but sometimes, when inflammation begins, the system immediately falls into a cold stage, like fever;—exactly as happens in the cold stage of an intermittent; so that the local inflammation appears simultaneously with the constitutional symptoms.

*Relation between the General and Local Signs.*—The general symptoms are usually proportionate to the intensity and the extent of the local inflammation; and likewise to the importance and sympathies of the organ affected. Sometimes, as I have already mentioned,<sup>a</sup> the general symptoms are disproportionate in their violence, and likely to mislead us in forming a prognosis of the case. If an individual have a temperature of 107°, and a pulse of 160, he may be inferred to be in eminent peril, provided the inflammation were not known to be inconsiderable, or seated in a part not at all necessary to life,—not at all of importance to the system; whereas, the same derangement attending inflammation of an important organ, or attending a very extensive inflammation of another organ, even not so important to life, would point out the greatest danger. It is obvious, therefore, that we are not to depend upon one symptom,—one circumstance, in a case; but must always take into view as many particulars as we can ascertain, in considering the question of inflammation.

*Disturbance of Function.*—Besides these local and these general symptoms, the functions of the part inflamed are disturbed. If the brain is inflamed, there is delirium; if the lungs are affected, dyspnœa is present; if the stomach be inflamed, vomiting is an urgent sign; if it be the intestines, constipation or diarrhœa usually attends it; if it be the bladder, there is a frequent and painful desire to make water.

*Changes in the Blood.*—It is not, however, merely these disturbances,—these changes, that take place. The blood itself becomes changed in inflammation. The red particles separate so fully from the fibrin, that this fibrin generally remains colourless and transparent at the top; and when this occurs, it is said to have a "buffy coat." There must some change take place in the blood, for this phenomenon to occur; and as soon as a portion of blood is removed from the body, we find that some alteration has taken place; for such are the effects. Occasionally the fibrin—white above and clear from the red particles which are below—is drawn into such an excavated form,—its centre so depressed, that it resembles a cup; and such blood is called "cupped." Blood may be buffy *without* being cupped. The red particles may separate entirely from the fibrin, and leave a buffy coat; but sometimes, in addition to this, the fibrin is drawn into an excavated form; so that it is buffed *as well as* cupped.

*Coagulation of the Blood.*—Blood coagulates, when it has escaped from the body, whether it be warm or cold, in the air or in vacuo; diluted within certain limits, or undiluted, at rest or in motion. While within the vessels, rest, which causes a cessation of intercourse between the motionless portion and the general mass, always disposes it to coagulate. Coagulation is supposed to depend upon the escape of carbonic acid; it is said to be proportioned to the quantity of gas evolved;—the latter being given off during the coagulation, and ceasing to escape when the coagulation is complete. Galvanism and oxygen gas raise the temperature of blood; but do not affect its coagulation,—any more than mechanical agitation. The coagulation of the blood is ascribed, by John Hunter, to its life; by Mr. Thackrah, on the contrary, to its death; because the separation of a portion of the blood from the whole mass, by its escaping from a vessel, is likely to kill it if alive; because every change likely to impair life, such as debility and fainting, promotes coagulation; and because blood

<sup>a</sup> See Page 88.

frozen (which process is likely to kill it if alive), and again thawed, instantly coagulates. According to the experiments of Dr. Scudamore,—though others have not found the same results,—coagulation appears, in most cases, to be attributable merely to the escape of carbonic acid. This hypothesis, however, is known to be erroneous; since the quantity which escapes, exercises no influence upon the phenomenon of coagulation; and as coagulated blood, or fibrin, becomes vascular, we can hardly, if the fluid be alive, regard a coagulum as necessarily dead. Large quantities of blood are found fluid in every dead body:—showing that the simple loss of vitality is not sufficient to cause coagulation. Indeed, the blood of the heart and vessels is found, most frequently, in opposite states;—fluid in one part, and coagulated in another; yet it is all equally dead. From all these contradictory circumstances, I regard the coagulation of the blood as quite unconnected with its vitality or its lifelessness, and as entirely a chemical result. That it is influenced, however, by the vital properties of the containing vessels, is possible; but these properties may operate upon the blood, in this respect, as a mere chemical compound; and even if it be alive, and they influence its life, still the influence, as far as respects coagulation, may in effect be chemical.

The blood generally coagulates in the living body, on escaping from its vessels, and even in its vessels, if its motion be prevented by ligatures. When it does not, its subsequent escape from the body almost always produces instant coagulation. John Hunter mentions the coagulation of blood let out from the tunica vaginalis; in which it had lain fluid for sixty-five days after a wound. It almost always coagulates, likewise, in the vessels which run through healthy parts to others in a state of mortification; and in large vessels adjoining a pulmonary abscess;—in which cases, the *final* cause is prevention of hæmorrhage. The *efficient* cause, however, in all these examples, is unknown. In all of them, the blood is still in contact with living parts; and in the two last, it is not at rest till it coagulates. John Hunter mentions that, after mortification of the foot and leg, he found the crural and iliac arteries completely filled with strongly coagulated blood; and adds, that this could not have arisen from rest; because, if that were the case, the same thing ought to happen in amputation, or in any case where the larger vessels are tied up. Besides, coagulation after extravasation, or when a portion of blood in a vessel is included between two ligatures, is not an invariable occurrence. These facts, in addition to those before stated, show that fluidity or coagulation is not dependent on the simple presence or absence of vitality.

When blood is drawn, the serum easily separates on the coagulation of the fibrin; but the latter coagulates before the colouring particles have time to fall to the bottom; and, from entangling them, acquires a red colour;—thus forming the crassamentum. If, however, the fibrin coagulates slowly, as in the case of a phlogistic diathesis, and pregnancy, the greater specific gravity of the cruor detaches it very considerably from the fibrin, which remains colourless above;—constituting what is called “the inflammatory coat, crust, or buff.” In the phlogistic diathesis, both the fibrin and the serum are more abundant, and the blood lighter. The receiving of it into a shallow vessel, and the rapidity of the stream, greatly affect the rate of coagulation; so that one portion of the same blood *coagulates slowly when drawn quickly*, and another *quickly when drawn slowly*.

The appearance of the buffy coat does not *arise* from slow coagulation, though *increased* by it; for, of two portions of the same blood, one has afforded no buffy coat, although it remained fluid at least ten minutes after the buffy coat began to be formed on the other. If, as appears from Mr. Hewson’s experiments, the buffy coat arise from the thinness of the fibrin, while the red particles continue of their usual weight,—the above circumstance proves, that slow coagulation is not altogether dependent on mere thinness of the blood, though generally connected with it, and proportional to it. Yet, when the blood is thin, rapid coagulation, by means of a slow stream, may prevent the formation of a buffy coat;—by not allowing time for the difference between the weight of the fibrin, and that of the red particles, to

effect a separation;—the slower the coagulation of thin blood, (occasioned, for instance, by rapid bleeding,) the greater will be the buffy coat.

The different cups of blood drawn in an inflammatory disease, may vary as to the buffy coat, according to accidental variations in the stream; but generally it is the *first* cup that abounds in buff, and frequently the *last* has none. This occurs when there is no difference in the stream. Sir Charles Scudamore finds much more fibrin in buffy blood; and consequently concludes that, not merely the *thinness* of the blood, (as Hewson found,) but likewise its *quantity* may vary during the flow of blood. Dr. Scudamore did not find a buffy coat in blood drawn immediately after violent exercise.

The blood of different brutes coagulates in different periods of time. Mr. Thackrah imagines the rapidity of coagulation to be inversely as the strength and size of the animal. Thus, while healthy human blood coagulates in from three to four minutes, the blood of the horse and ox coagulates in from two to fifteen; that of dogs, sheep, rabbits, and fowls, in from half a minute to three minutes; and in mice and fish in a moment.

*The Blood in Pregnancy.*—Occasionally, this buffy appearance of the blood takes place (it is said) without inflammation. It is usual in pregnancy; but a pregnant woman may be considered to be in an inflammatory state;—not a state of actual inflammation; but the condition of the womb is really inflammatory. In pregnancy the whole body frequently wastes. The eyes become hollow; and the whole health, for the most part, suffers a little. The pulse becomes very quick,—quicker than in health; and all the blood-vessels of the womb become greatly enlarged. The womb itself, if it be not in a state which justifies us in calling it *inflammatory*, is, nevertheless, in a state of activity so great, that it comes as near to inflammation as possible. When, to look at other periods of generation, animals are “in heat,” and copulation takes place, the genital organs become violently red,—violently hot,—perhaps blackened with blood,—as if they would burst; and all the blood-vessels throb. If that state ought not to be called “inflammation,” still it is very clear that it nearly approaches to that state; and whatever word be employed, we must look at it as physiologists and pathologists. We cannot wonder, therefore, that in pregnancy the blood should frequently be buffy.

*Absence of the Buffy Coat.*—But this state of the blood is sometimes absent in inflammation. We may find a patient undoubtedly labouring under a most violent inflammation; and, on using the remedies for that affection, the most decided effects, and even cure, may result; and yet no buff may be present in the blood. This is by no means uncommon in bronchitis; where a patient has a rapid pulse, and great heat of body; cannot turn in bed without coughing; suffers under a difficulty of breathing,—so that he is obliged to breathe in a shallow manner; cannot expand the lungs without extreme soreness, tightness, and violent cough. The tongue is white, and violent pyrexia is present; and if bleeding be resorted to, instant relief is afforded; so that both the symptoms and the treatment prove the existence of inflammation. In many cases of bronchitis, the blood will not show the slightest morbid appearance; whereas if, instead of the lining membrane of the air-tubes, it were another membrane that was inflamed, (as, for instance, the pleura,) the smallest quantity of blood that could be taken away, would most likely show an intensity of buff, and be cupped in addition. The absence of this buffiness of the blood, is by no means a proof that there is not inflammation; but, if it be present, it is generally in proportion to the violence of the inflammation. If doubt existed as to whether the patient was labouring under inflammation or not, the appearance of this buffiness might justify the conclusion, that the symptoms which were suspected to be inflammatory really were so. The absence of it is no proof that inflammation does not exist; but the presence of it will, in doubtful cases, very much confirm your conclusions, that the symptoms treated were inflammatory. The buffiness, however, is not necessarily in proportion to the *danger* of the inflammation; for, in acute rheumatism, where there is no immediate danger, unless complicated with internal inflammation, the blood will generally be intensely buffed,

and not unfrequently intensely cupped at the same time. We are usually, therefore, to consider this as a mark of inflammation, or of an inflammatory state; but its absence will not warrant us in saying that there is no inflammation; and the intensity of the buffy or cupped state, is not to be considered as a proof that the inflammation is of an exceedingly dangerous character.

Many particular circumstances are necessary to be observed with regard to this phenomenon. The first cup will often be buffy; while the second, taken within a minute or two, is much less so, or perhaps not at all. When this circumstance occurs, I believe the difference generally arises from the amendment of the patient; for the beneficial effect of bleeding is sometimes very striking;—it sometimes checks the inflammation immediately. One may conceive that a certain portion of benefit, in such cases, takes place before half the blood we intend to withdraw is removed; and when the second cup exhibits less buffiness than the first, we may ascribe it to the actual amendment of the patient.

*Relation between the Time of Coagulation, and the Buffy Coat.*—The buffiness of the blood is certainly affected by the slowness of the coagulation; so that if the blood do not flow freely at first, but does afterwards, the quick coagulation of the first cup may not give the red particles time to subside; and this may prevent its being buffy. Hence we see that the quick or slow coagulation of blood must effect its buffiness. As blood coagulates the sooner the more it is exposed, and therefore the more slowly it trickles down the arm, increased quickness of coagulation may prevent buffiness in blood which would otherwise present it; and when it comes out more freely into the second cup, it may coagulate more slowly; and then, if there be a disposition to buff, the buff will form; so that it is not at all uncommon to have no buffiness in the first cup, but to find it in the second. Therefore, although a patient may have improved from bleeding, and have a disposition to form less buff in the second cup than in the first, yet the accidental circumstance of its trickling down the arm into the first cup, may give rise to an opposite occurrence, and may counterbalance the operation of the benefit. Buffiness may be shown in the first cup, and none in the second, from the improvement of the patient; or we may have no buffiness in the first, and find it in the second,—notwithstanding that the patient has improved,—from the accidental circumstance of the second cup coagulating less speedily than the first.

*Dr. Stoker's Experiments.*—But although the quickness and slowness of coagulation may affect the formation of buff, yet they are not the cause of it; for it has been known that, of two portions of the same blood, one has continued fluid ten minutes after the other had begun to form buff, and yet has shown no buff. When the stream of blood is exactly the same, causing the blood to flow into cups with equal rapidity, we sometimes find the difference of buff to be exceedingly great; and sometimes the buffiness is the same when one cup has coagulated very slowly, and the other very quickly. Dr. Stoker has given us some experiments upon this point, in his "*Pathological Observations.*"<sup>a</sup> He has furnished twenty-seven experiments; in fifteen of which buff was formed, while in the other twelve it was not. Among the twelve in which no buff was formed, no coagulation took place in three of them in less than from twenty to forty minutes; and in four there was no coagulation for eight minutes. There was abundance of time, through the slowness of coagulation, for the red particles to separate from the fibrin, and yet the result was as I have stated; whereas, in the fifteen in which buff was produced, not one specimen delayed to coagulate longer than fourteen minutes, and in all but three coagulation took place in five minutes, and yet buff was produced. The real cause, therefore, of the buffiness of inflammatory blood, certainly is not the slowness of the coagulation; but from what it proceeds I do not know. It may be owing to the thinness of the fibrin; for it appears to be a fact, that the fibrin of buffy blood is both thinner and more abundant than that of other blood. If it be thinner, one may conceive that the red particles will more easily separate from it,

<sup>a</sup> Published in the year 1829.

and subside to the bottom. That *may* be the reason; but I do not say it *is*. As the quantity of fibrin is known to vary during the flow of blood, so probably may the thinness, and this may be the reason why blood which showed buffness in the first cup, exhibits none in the second;—the blood being thicker, the red particles do not so easily separate. At any rate, the buffness of the blood is not proportionate to the slowness of the coagulation. Dr. Stoker's experiments confirmed the opinion I had previously formed from observation and reading; yet I believe it is true, that buffy blood generally coagulates more slowly than other blood; although I do not ascribe the buffness to this circumstance. The slowness of coagulation may be in a great measure owing to the thinness of the fibrin; for if the fibrin be thin, it will probably be less disposed to solidify. It is said, that the mere celerity of the circulation does not effect any changes in the quality of the blood;—that it is not because the pulse is quick in inflammation, that the quality of the blood changes.

But although inflammatory blood, showing buff, generally coagulates more slowly than other blood, yet the buff coagulates if there be strength of body very firmly,—more firmly than the crassamentum in health. The firmness and the cup-like form, are usually proportionate to the strength of the patient; but it is to be remembered, that the firmness of the coagulum is sometimes very great, without there being any cupped appearance. The firmness and cupped form are said to be greater in inflammation of fibrous membranes,—such as aponeuroses, ligaments, and tendons,—and in inflammation of serous membranes, than of other parts.

If it so happen that the buff of the blood be not firm, then the blood is said to be “sizy;” and when the coagulum of blood is soft, whether it be buffy or not, the serum will be found too abundant.

The cupped appearance of the blood, as well as the buffness, is very much affected by the size of the vessel into which we draw it. If we extract the blood of a patient into a tea-cup, we have an infinitely greater chance of finding it buffy, than if we draw it into a hand-basin. The larger the vessel the less is the disposition to form the buff, and likewise to form the cupped appearance. For accurate observation, blood should certainly be drawn into small vessels.

*Blackness of the Blood.*—It is a general observation, that the blood is very black in the inflamed parts; although it is more *arterial* in the *surrounding* vessels; since it passes through the capillaries into the veins *without* acquiring the venous character. Leeches, at their first application to an inflamed part, abstract black blood; but after several applications it becomes bright.\* I have observed this frequently, and I presume it arises from this circumstance;—that the blood, from moving slowly in the inflamed spot, acquires more of a venous character. I have known the blood, times innumerable, to be black, on the first application of leeches; and I once knew the blood, in a case of chronic inflammation of the liver, highly offensive; so that almost as soon as it was removed, it passed into a state of putrefaction; but as leeches were applied day after day, it became brighter and brighter, and at last regained its natural odour and nature. It would be wrong to consider inflammation as merely affecting the solids; it affects likewise the blood itself.

*Duration of Inflammation.*—Having spoken of the *effects* of inflammation, I now proceed to consider its *duration*; and this is very various,—depending much on its intensity. If an inflammation be exceedingly violent, it cannot last long; but if that be not the case, it may last a great length of time. Inflammation may exist for only a very few hours, and may certainly destroy life in the course of a day. It is sometimes so rapid, that a person shall be well in the afternoon, and die from it before the next morning is much advanced. Pericarditis may occur suddenly in the evening, from exposure to cold, and end in death by the next morning. In-

\* It is a curious fact, that blood drawn by leeches never exhibits the buffy coat. It seldom appears on blood that has been removed by means of cupping-glasses; but I have seen it take place.—Dr. Watson's *Lectures on Inflammation*; “*London Medical Gazette*,” Volume 27; Page 339.

flammation may be so acute as to destroy life in a few hours, without any mortification, but simply from its own intensity. A child is sometimes seized with a violent rush of blood to the head;—its eyes will become red; its face flushed; and its head distracted with violent pain. It screams; and death ensues in the space of one or two minutes. The same thing will happen in adults. After death, a great quantity of blood will be found within the cranium, and externally to it. If this state be inflammatory, which is questionable, it certainly proves that inflammation may be almost momentary; and that it will destroy life in this sudden manner.

But inflammation, if it be not violent, may last for many months, and even years; for if it remit, it may often be tolerably violent, and yet continue for a very long time;—its severity not remaining the same during the whole of the period. If it once degenerate into the chronic form, it may last indefinitely: and when it does so, it generally induces various changes of structure, which I will hereafter mention. When a part has been once inflamed, the redness will occasionally remain some years, without any pain or any heat. We frequently see this after burns, and after cutaneous diseases. A portion of a scar will remain exceedingly red;—the vessels would appear to be in a state of passive dilatation. There is no pain, no heat, no tenderness, but extreme redness; and this—after it has existed a year or two, or perhaps longer—will sometimes decline; and the vessels will at last gradually recover their natural tone. After ulceration, the skin will frequently remain of a red colour, perhaps of a very dingy red, and almost of a brown colour. In the case of a person who has had a sore leg, the portions corresponding with the spots of ulceration are frequently very red, brown, variously discoloured, or perhaps nearly black.

## SECTION V.—RESULTS OF INFLAMMATION.

Inflammation may terminate in complete health of the part. The part may, in a direct manner, regain its former state; and when this is the case, it is said to terminate in “resolution.” Generally, however, when there is this resolution,<sup>a</sup> there is some increased secretion, either at a distant part, or (if the part affected be of a secreting character) in that part itself. If it be a serous membrane, there is more or less effusion; if it be a cellular membrane, there is a more or less œdematous condition, which can be observed externally. But if these effects be very slight,—only temporary,—perhaps no inconvenience is produced; and the termination of inflammation is then said to be in “resolution.” If, however, it be a serous membrane that is attacked, and there be a copious secretion, it is said to terminate in “effusion.” If it be a cellular membrane that has been inflamed, and it does not terminate in resolution, a new fluid is formed, called “pus;” and the formation of this new fluid is denominated “suppuration.” If it be a mucous membrane which has been affected, a great discharge either of mucus or pus supervenes; so that suppuration either from a cellular or mucous membrane may occur. It is actually pus that is formed, in inflammation of a mucous membrane; pus likewise may even be produced by the interior of a vessel. But it is right to say, that although authors call these phenomena “terminations,” yet these copious secretions are not necessarily terminations; and that when they begin, it is not a matter of course that inflammation shall end. Although the part may suppurate, or fall into a state of effusion, these processes may, nevertheless, be inflammatory. It may still be desirable to go on with anti-inflammatory measures;—since heat, pain, tenderness, and all the marks of inflammation may continue. We ought, I think, rather to say that inflammation, sooner or later, induces these changes; or that these occurrences take place in inflamed parts;—whether the inflammation subsides or not. Inflammation may terminate, however, not in health, either directly or after these processes, but in *death*, either general or local. It may destroy life, without the occurrence

<sup>a</sup> From “*resolvo*,” to *loosen*.

of any farther change. It is very common to see persons die of enteritis, without mortification, or any other change. It sometimes happens, however, that inflammation does not destroy general life, but the life of the individual part; and then it is said to terminate in "mortification." But the inflammation may still continue,—not in the dead part, but in the parts around; and may extend farther, till more parts die.

[Before proceeding to the individual effects of inflammation, it is necessary to understand that, according to the accepted theory, in *every* degree of inflammation, contradistinguished from congestion and irritation, effusion must necessarily occur; the quantity of which obviously varies directly with the intensity of the action. This may be regarded as a law established by the numerous observations of Kaltenbrunner. The stages of irritation and congestion may pass away without the occurrence of any extravasation; but he has uniformly observed, that so soon as the *stasis* of the blood in the capillaries, which constitutes true inflammation, takes place, so soon does the *liquor sanguinis* permeate the coats of the vessels, to gain and occupy the surrounding cells. It is therefore certain that, although inflammation may end in recovery by *resolution*, an exudation of the more fluid part of the blood has taken place. This, of course, will vary with the character of the structure in which inflammation occurs;—being adhesive albumino-fibrin in serous membranes, glutinous mucus in mucous membranes, and consisting, in the parenchymatous structure of organs, for the most part of inspissated *liquor sanguinis*.—*T. Williams.*]

*Resolution.*—I will now speak particularly of these various "terminations," as they are called; the first of which (resolution), is really a termination. When an inflammation is resolved, all the symptoms decline, and no fresh symptoms arise; and this is essential to the character of resolution. While the inflammation is going on, the urine is generally high-coloured, and clear; but when it subsides, there is usually a copious red sediment. The reason assigned for this by chemists, is the following. Urine in a healthy state contains, besides other matters, lithate of ammonia, and a yellow colouring matter; which, according to Liebig and others, is believed to be isomeric with lithate of ammonia; both of which remain in solution under ordinary circumstances. If, however, the urine undergoes any change in its constitution, from the existence of diseased actions in the system, these constituents become, to a certain extent, insoluble;—forming a precipitate, the colour of which pretty accurately indicates the nature of the changes that are taking place. If the colour of the precipitate be *pink*, it is owing to the action of nitric acid (which, in certain diseased states, is found in excess), or a portion of lithate of ammonia, converting it into purpurate of ammonia, and giving to the rest of the precipitate a pinkish hue. If the precipitate be *yellow*, then it consists of lithate of ammonia alone, slightly tinged by the yellow colouring matter of the urine. If the precipitate be *red* (lithitious), it is owing to the presence both of purpurates and colouring matter; which form a red colour, when they are mixed together. During inflammation, the lithates of soda and ammonia are in excess in the urine, and nitric acid is formed; which, acting on the lithic acid, produces the purpurates. These give a pink tinge to the lithates, whether they are in solution or precipitated; and this pink colour, by admixture with the yellow colouring matter of the urine, is changed to red. The reason why the urine is red without sediment, during the progress of inflammation, is this.—the same substances are in the urine, but held in solution during the activity of the complaint; but when it declines, an excess of lithic acid is formed,—producing super-lithates, which are known to be insoluble; and therefore a great portion of them falls down in the form of a precipitate. Hence the appearance of the red sediment. This is the explanation given by one who, perhaps, understands these things better than any other man in Europe;—I mean Dr. Prout. The deep-red colour, with transparency, during the activity and copious red deposit on the termination of the disease, are respectively characteristic of inflammation.

*Effusion.*—If, however, the inflammation do not terminate in resolution, but produce such an effusion as from its quantity may do harm, the symptoms of the

inflammation may subside, and a fresh set of symptoms may come on, from the compression of the parts. If the pleura, for example, has been inflamed, and the inflammation induces at last copious effusion, after the pleuritis has subsided, a fresh *series* of symptoms supervene, dependent upon compression of the lung. When there is this excessive effusion, however, in a serous membrane, there is generally something more. Liquor sanguinis is usually thrown out;—sometimes forming layers,—sometimes diffused in the serum, and forming flocculi; so that the serum becomes turbid. When albumino-fibrin is thus poured out by a serous membrane, it is at last often entirely absorbed; while the fibrin remains, and frequently we find fibrin where there is no appearance of serum;—the serum having been absorbed. Professor Thomson, of Edinburgh, says that he has seen lymph lying on a serous membrane, within four hours after he had induced inflammation. Sir Everard Home says, that he has known an effusion of albumino-fibrin form vascular adhesions in the course of twenty-four hours. Sometimes the effusion which occurs, is purulent. Thus the pleura, the pericardium, or the tunica vaginalis, may be filled with pus; and sometimes with a mixture of pus and serum.

*Suppuration.*—The third effect of inflammation is “suppuration.” When this occurs, the pain generally ceases, but the swelling increases; and is marked, for the most part, by the sense of fluctuation which it imparts to the finger. This fluctuation is not always discoverable at first; but becomes more and more decided, as the fluid increases. The pain, however, does not always cease. It may decline at first; but, as the fluid increases, considerable pain may come on from tension;—the part becoming exceedingly tense, from the quantity of fluid; which is afterwards absorbed, or escapes either by art or nature. Besides this, where there is suppuration of a cellular membrane, or of any organ, fresh symptoms from pressure may occur;—just as in effusion from a serous membrane. If the suppuration be extensive, shivering may come on, and what are called “rigors” take place; followed by, when matter is being formed, great heat and sweating,—constituting “hectic fever.”

*Hectic Fever.*—This hectic fever is marked by a quick, but weak pulse; by heat of the whole surface; but particularly heat, with a red flush, upon the cheeks, the palms of the hands, and the soles of the feet. Sometimes the whole of these are red; but more frequently the redness is partial, forming patches; so that a portion of the cheek, the size of half-a-crown, may be intensely red, while all around is of the usual pale character. In addition to these symptoms, the patient has profuse sweating; so that as soon as he falls asleep, he is almost sure to fall into a sweat. Free perspiration likewise happens often during the walking state. These symptoms are generally aggravated at night, and frequently also at noon; and, indeed, at any time when food is taken. The effect of sleep upon the sweats is remarkable. If a patient fall asleep but for two minutes, although he may not know it, it is very common to find these sweats break out. They are frequently very partial;—being particularly observed about the head and chest.

In hectic fever, when suppuration is going on, the urinary deposits are of a pink colour. The chemical changes are precisely the same;—the purpurates acting upon the lithates, and producing this pink colour. This pink colour is not changed to red; because the yellow colouring matter of the urine is absent, and therefore the pink of the purpurates and lithates remains unchanged. The intestines often pour forth a fluid as abundantly as the skin, and then there is purging; not unfrequently the purging alternates with the sweating; so that if there be an increase of the sweating, there is a decrease of purging; and *vice versâ*. This sweating and purging is called “colliquative,”—“melting the patient down;” and hence the name.\* The alimentary canal often becomes inflamed; and when a patient who has laboured under this state is examined after death, the mucous membrane appears red and ulcerated. The tongue at length becomes red. We may see it yellowish, or of a deep brown colour; but for the most part it is red, either on the surface, or

\* From “colliqueo,” to melt.

at the tip, or at the sides and tip. The mind generally becomes very quick: the patient is excessively alive to every thing; and, at the very last, a degree of delirium takes place. When that occurs, it is usually the precursor of a fatal end. I need not say there is usually extreme debility and wasting of the body. It is to be remembered, however, that these symptoms (called "hectic fever") may occur without any suppuration. They will occur, I know, from mere depression of mind; they will frequently occur in women from excessive suckling;—from suckling too much, or suckling too long. All these symptoms, without suppuration, will sometimes remain for a great length of time; and the patient, at last, by proper management, do very well.

*Abscess.*—Sometimes the matter is collected together in a cavity;—forming what is called an "abscess." [In explaining the formation of an *abscess*, it is necessary to remember that the *invariable* result of inflammation is—the effusion of *liquor sanguinis*, differing in its quality, according to the varying condition of the system. When inflammation occurs, therefore, in any given part, circumscribed by defined limits, the cells of the tissue become infiltrated, at the spot in which the action is most intense;—softening of the original structure succeeds; and a more or less perfect *solution* of the proper tissue takes place, in the inflammatory effusion. This change constitutes that condition, which, in scientific medicine, is regarded as an *essential* preliminary to the process of absorption under every combination of circumstances. The doctrine, first propounded by Hunter, which supposed the previous *solution* of the *substance* of a part as unnecessary to its absorption, was subverted by the researches of Mr. Key, published in the Transactions of the Medico-Chirurgical Society. The views of Mr. Key have been likewise advocated by Dr. Prout; who puts it forth as a principle of universal application, that the *solution* of a part is an essential pre-requisite to its absorption. Physiology presents us with numerous instances of interest, which might be advanced in confirmation of this view. The *yolk*, in immediate contact with the beautiful web of the area vasculosa, undergoes liquefaction before it passes into the vessels, to fulfil the purpose of nutrition. The lymph is taken up by the absorbents in a perfect state of liquidity. Thus, then, the first steps in the formation of abscesses are rendered intelligible. This disintegration, induced by the softening, soon becomes limited by more active inflammation—a separation is worked out between the *disorganized* and the surrounding living parts, by the production of a sacular membrane—which in surgery is called *pyogenic*.<sup>a</sup> It consists, at the beginning, of the cells of the encircling structure infiltrated with a fibrinous deposit—which subsequently acquires the characters of membrane.—It is supposed to exercise the function of absorption and secretion;—thus renewing the contents of the abscess.—*T. Williams.*]

This pyogenic membrane, together with the adjacent soft parts, become gradually absorbed at one particular point of the abscess, nearest to the surface, or some principal outlet of the body; wherever, in fact, the easiest exit for its contents is to be found;—abscess of the liver, for example, may either point outwards towards the surface, or upwards towards the lungs; and, after producing absorption of the intervening diaphragm, discharge its contents. Such, at least, was the opinion of Hunter; it is however certain, that there are other circumstances to be considered;—such as the structure of the affected part, and the greater or less facility with which it takes on inflammation and ulceration. When there is danger of pus escaping into a cavity, or part of the body where serious consequences would result (as, for instance, into the peritoneum), then a great deal of additional lymph is frequently thrown out for the purpose of gluing the various parts together;—in order to prevent, as much as possible, the escape of the pus in an improper direction. Thus nature usually thins the walls of an abscess at that point which is most eligible for the escape of the pus; and thickens them where it would be dangerous for the pus

<sup>a</sup> Pus—yellow.

to escape. This extraordinary provision of nature, may truly be considered as one of the most wonderful phenomena which claim the attention of the pathologist.

The absorption at the former point, wherever it may be, goes on. If it be near the surface, we see the chief swelling at one particular part; and the collection is said to "point." At length a minute opening is formed, and the matter escapes. When the latter occurrence takes place, and the cavity is thus opened, minute red granules, highly vascular, soft, and covered with pus, are seen within. In fact, they secrete the pus. Sometimes the opening at which the matter escapes, although small at first, enlarges; absorption takes place to a great extent; ulceration runs on to a considerable distance, and perhaps lays bare the cavity very much.

These red granules grow larger and larger, till the cavity is filled up. This process is called "granulation." When the cavity is entirely filled up, portions of skin form upon its surface, and portions of the surrounding skin are prolonged into them; so that there is a double source of new skin. Fresh skin appears in insulated points; and the healthy skin around shoots prolongations into it. In this way the surface of the granulations becomes covered with skin, and is healed. The smaller the granulations are, the better; for if they be large, they are generally spongy; in which state they are popularly called "proud-flesh."

From the loss of cellular substance which takes place in the formation of the abscess, (for the cellular membrane is more or less destroyed,) and from the contraction of the new parts (for these granules, which were very vascular at first, become less and less so), after the healing takes place a depression is seen. If it be a very minute abscess,—such as is only called a "pock," as in small-pox,—there is merely a little depression,—a pit; but if it be a more extensive formation of matter that has taken place, "scars" result. They are exactly the same thing, only on a different scale. The contraction of the new parts, and the loss of the cellular membrane, are sometimes so great, that the joints cannot be extended; and the arm becomes bent to the body, or the fingers bent down to the hand.

Pus is sometimes collected in an abscess, in this way, without any lining of lymph; but when the latter is absent, the pus is almost always diffused. Pus is often formed in the cellular membrane in a diffused manner,—so as to run to a great extent, and do very serious mischief;—producing, wherever it spreads, new inflammation, and the most frightful devastation. This is observed in that form of erysipelas styled "*erysipelas phlegmonoides*." Where suppuration takes place in the cellular membrane, uncontrolled by a cup of lymph, it often runs on extensively; and sometimes a whole arm, or a whole thigh, is in this way covered by a sheet of matter.

*Suppuration without an Abscess.*—Sometimes, however, there is a formation of pus, and an absorption of the skin and cellular membrane, without any collection of matter. This is seen every day in the case of the throat, and sometimes upon the skin itself; but more frequently upon a mucous membrane. If the latter be attacked by a slight inflammation, the epithelium may be absorbed, together with a small portion of the mucous membrane;—in fact, there may be an ulcer; and that ulcer will secrete pus, without there being a collection of matter underneath. In an abscess, the matter is formed in the cellular membrane, or in a solid structure, and tends outwards; but frequently, in a mucous membrane, the process goes on inwards. Nothing is more common than to see this in the throat. The surface, which is a little inflamed, becomes abraded; matter is formed upon it; and in that way an ulcer is formed, without the previous existence of an abscess. If the part heal, it is afterwards filled up;—in the same way as if the matter had been collected in a cup, in the cellular membrane.

*Characters of Pus and Mucus.*—Pus, if healthy, is an opaque fluid, yellow or white, homogeneous, short, and creamy; so that if we take a drop between our fingers and separate them, it breaks. The drop divides into two,—does not hang in strings. If it be perfectly healthy, it is bland to the taste, and without smell. Some say it is rather mawkish; but one never thinks of tasting it, except in the case of a gum-boil, or other suppuration in one's own mouth. It is said to be

neither acid nor alkaline; although, by exposure to the atmosphere, it turns sour. It is also insoluble in water. It contains globules; and hence it is distinguished from pure mucus, by being placed between two bits of glass, and then looked through at the sun. From the existence of the globules, we have an iridescent appearance;—resembling the colours of the rainbow. This is not the case with mucus; for mucus contains no globules. It is said, however, that when pus is first secreted, it is not globular; and that these globules do not appear in it, till it has been poured forth from the vessels for fifteen minutes. Mucus, again, is not short, like pus. If we take a portion of mucus between the finger and thumb, and separate them, it drags out into threads.

Persons have endeavoured to discover the difference between pus and mucus by chemical tests. John Hunter says, that he found pus easily coagulate by a solution of muriate of ammonia; but that mucus would not. Dr. Darwin (Junior) says, that a solution of caustic potass does not dissolve pus; but makes it a viscid semi-fluid substance; stringy, like mucus;—not dissolvable in water; but resembling the diseased mucus of the bladder. When the bladder is in a state of chronic inflammation,—when the mucous membrane is in a state of cystorrhœa, and there is a great discharge of mucus from the surface, its mucus is very ropy, and may be dragged out to a great length; and this is the appearance which pus exhibits, if it be mixed with a solution of caustic potass. Dr. Darwin also says, that the same effect is produced, by adding to the pus sulphuric acid; whereas, if we add these acids to healthy mucus, small flakes are produced, and not a stringy semipellucid substance. On the other hand, two modern French writers (Andral and Baumes) deny this distinction. Then, again, another chemist (Grasmyer) says, that if pus be triturated with an equal quantity of water, and this combined fluid be then mixed with an equal quantity of carbonate of potass, a jelly is produced in a few hours; but that is not the case with mucus. Pus in general sinks in water, but mucus generally does not; and if pus be diffused in water, the water becomes uniformly white.

As to all these distinctions, however, the fact that pus and mucus are convertible into each other, is established by modern organic analysis. Mucus may be diseased, so as to be something like pus,—puriform; and they will run into each other by insensible degrees. In disease of the lungs, the distinction between pus and mucus has been thought most important, as tending to show whether ulceration exists; but here the two secretions are continually mixed together. When there is an abscess of the lungs, or a number of abscesses, and matter is discharged from them, a quantity of mucus is at the same time secreted from the bronchial tubes; so that the pus and the mucus are expectorated together; and in proportion as the former surpasses the latter in quantity, or the latter exceeds the quantity of the former, the characters of the one or the other are presented. If the quantity of mucus be very considerable, the pus may be borne up by it in water,—not allowed to sink. Besides this, there may be an abscess in the lungs; and there may also be an excavation secreting, not pus, but mucus. The lining membrane of the cavity in the lungs—at least, if fresh ulceration have not taken place—may secrete mere mucus. Again: every mucous membrane which is inflamed, may produce absolute pus; so that pus may be discharged from the lungs, when there is no ulceration at all; while, on the other hand, there may be ulceration of the lungs; but the lining membrane of the abscess may have become of such a mucous character, as to secrete real mucus.

*Analysis of Pus.*—With regard to the constitution of pus, Schwilgué (who is one of the last that has analyzed it) says that it consists of albumen, extractive matter, fatty matter, soda, muriate of soda, phosphate of lime, and some other salts. When pus is scrofulous, it is said to have more soda and muriate of soda, than healthy pus. Pus was once imagined to consist of the dissolved solids. Seeing that a cavity existed, it was imagined that the solids were melted down, and turned into pus. But frequently pus may appear when there is no ulceration at all; nor is the formation of pus in proportion to the loss of the solids. From a small

abscess, there may be an immense secretion of pus, if by chance the abscess do not heal; and yet it does not extend. The pus is a new *excretion*. Whether globules are formed in it,—whether it be perfect immediately or not,—is of no consideration. The fluid from which pus is produced is a secretion. It appears to possess solvent properties; for John Hunter found dead flesh dissolve very readily in pus. He put an equal quantity of dead flesh into pus, into jelly, and into water; and he found the portion put into pus dissolve very readily, while the portions put into jelly and water did not. Hence it would appear, that pus is useful in dissolving the solids when they die.

Healthy pus is called by the old writers “laudable.” I recollect, when a student, hearing good pus, instead of being termed “*healthy* pus,” commonly called “*laudable* pus,”—“*praiseworthy* pus.”<sup>a</sup> Healthy pus should abound with globules.

If the globules be deficient, and the pus be watery, then we have what is called “*ichorous*” pus.” But there may be other differences in pus, besides a deficiency of globules. If it be thin and bloody, it is called “*sanious*,” and it is called “*serofulous*” if there be in it little curds; which curds, very possibly, are shreds of lymph. Pus sometimes very much resembles mucus. It does not abound sufficiently in globules, is glairy or muciform, and will hang out in little strings. When mucus, however, becomes something like pus, we call it “*puriform*.” Pus frequently becomes fetid. This particularly occurs if a bone be diseased; but in suppuration of the tonsils, likewise, it is not uncommon for the pus which escapes, or is let out by a lancet, to be most horridly fetid. Generally, however, it is when pus comes from the bone, or the immediate neighbourhood of a bone, that it assumes this fetid character.

We have already mentioned in how short a time albumino-fibrin has been seen effused on a serous membrane;<sup>c</sup> and pus also has been seen to form in a few hours. It has been seen produced by a mucous membrane, in a few hours after inflammation has been set up; and when an abscess has been produced, matter has been formed in so short a time as from twelve to eighteen hours from the commencement of the inflammation.

*Mortification.*—The next termination of which I shall speak, is “*mortification*.”<sup>a</sup> This is shown by the part becoming of a darker red than before. When a part is about to mortify, it grows of a dingy red; from red it becomes purple, and then black; and when it is once dead, it changes from the decomposition of the matter to a green colour, and various other hues. The pain ceases,—the part becomes cold,—and, if it be the surface, we often see vesicles; which, although they are frequently filled with a pale fluid, yet are more frequently filled with a bloody serum. If it be the skin which is mortified, it becomes variegated; and perhaps the part crackles under the finger. From the extravasation of air, the swelling increases; the part has often a doughy feel. These are the *local* symptoms; but *general* symptoms take place. There is extreme prostration of strength, with extreme restlessness. The face becomes ghastly; the pulse becomes rapid and exceedingly weak,—perhaps intermitting and irregular. There is a general fall of the temperature of the body; and a cold clammy sweat takes place. The tongue becomes brown or black;—the patient’s manner becomes exceedingly quick; and, frequently, a little delirium takes place. The cessation of the local, and of all the violent general symptoms, will take place just before death from inflammation, when that inflammation does not cause mortification, or any other local change;—

<sup>a</sup> This has been considered an absurd epithet; but it serves as well as any other to express what was meant; namely, that kind of pus which accompanies benign forms of inflammation, and which indicates that all is going on regularly, and promises a fortunate ending;—pus, in short, the appearance of which was to be commended. It is certainly not more absurd than the term “*healthy* pus.”—Dr. Watson, in the “*Medical Gazette*” for November 27, 1840, No. 678; Volume 27; Page 343.

<sup>b</sup> From *exors*, a thin, acrid fluid.

<sup>c</sup> From “*mors*,” death; and “*fio*,” to become.

<sup>c</sup> See Page 96.

although, when mortification occurs to any extent, the very same thing is observed. That is to say, the cessation of pain, the ghastly countenance, the rapid, feeble pulse, the extreme sense of debility, restlessness, and at last death, without any mortification, may happen,—without any other local change whatever. Frequently, from the symptoms of enteritis, we should imagine that mortification of the intestines had taken place; but, on opening the body, we may find no mortification,—nothing but intense inflammation.

When the parts inflamed become of a purple colour, and cold, and fall into incipient mortification, restoration is not impossible. Parts will recover that have become purple, and lost a portion of their temperature. Even parts which have been congealed, will recover by good management; but this, I believe, takes place in man and the other warm-blooded, more than in cold-blooded animals; and Professor Thomson, of Edinburgh, says that if a *whole* limb be frozen, it is never restored.

*Gangrene and Sphacelus.*—A still higher degree of mortification is called “gangrene;”<sup>a</sup> and the complete death of a part,—when it is gone irrecoverably,—is termed “sphacelus.”<sup>b</sup> In the latter case, the part is cold, senseless, black; and putrefaction follows. There are three degrees, therefore, of mortification;—the one where the parts are merely purple and cold; a second where things are more advanced, but the part is not absolutely dead; and the third, in which the part is really dead,—“mortification” being the generic term for all the three stages. When a part is dead, and putrefaction is begun, the progress of the latter depends very much upon external circumstances. The warmer the weather, of course the more readily will putrefaction take place.

*Separation of Dead Parts.*—If the part which is in a state of sphacelus be not important to life, it may be separated by nature from the body. The process of nature, here, is exceedingly wonderful. The large vessels, which go to the part, become plugged up;—a coagulum of blood forms in them, or adhesive fibrin is poured out from the inner surface; so that in one way or other the progress of the blood is arrested; the consequence of which is, that it coagulates to some extent above the plug, and the plug thereby becomes increased. Dr. Thomson (of Edinburgh) says, that a coagulum never extends higher than the first communicating branch; and that is what we should suppose. The blood coagulates behind the plug, nearest the heart; and therefore, we should not expect a plug to extend beyond the first communicating branch. Dr. Thomson has seen a vessel completely obstructed, without the formation of any plug at all;—the whole obstruction being produced by an effusion of lymph,—lymph which has become organized, and formed an internal adhesion. He has even seen an artery completely obstructed without any lymph,—without any plug; but simply from its becoming closely contracted;—so contracted that it would not admit a bristle. The contraction has formed as complete an obstruction to the blood as a coagulum, or a quantity of fibrin, would have done. He says that he has noticed the same circumstance in an amputation, where no ligature had been employed. The vessels have become so contracted, as not to admit of the introduction of a bristle; and have thus prevented all hæmorrhage. In whatever way it is done,—whether by a coagulum of blood, or by a plug of lymph forming an adhesion, or by the mere contraction of the vessels, or by any two of these,—such is the fact, that nature generally succeeds in preventing hæmorrhage from a mortified part, by obstructing the course of the blood in the larger vessels leading to it.

The process of separation is accomplished in this manner:—A red line appears at the boundary of the healthy part, which is nearest to that which is dead. This red line is a line of inflammation; and in it ulceration takes place, and gradually penetrates the healthy part, till a complete separation takes place; and in this way a whole limb is sometimes separated from the body.

*Necrosis.*—Of course I have been speaking of soft parts; but if a long bone die,

<sup>a</sup> From γρᾶω, to feed upon.

<sup>b</sup> From σφαλω, to destroy.

without any death, or any especial disease, of the surrounding parts, a new bone is formed around it. The process of nature, therefore, is quite different here, from that which is employed to separate a dead soft part. In this case, a new bone is formed under the periosteum, around the dead portion; and in this way the parts exterior to the new bone—the periosteum, the ligaments, and the cartilages—all become attached to it. When the old bone within the new one is completely loosened, an opening is formed in the new bone; ulceration takes place in it at one spot; granulations occur on the inner surface; and these granulations push the old bone through the ulcerated opening in the new one;—at least they tend to do so. The aid of a surgeon is frequently of use in assisting to draw out the old bone, and enlarge the openings in the new; but this is the process adopted by nature when a bone dies. It is called “necrosis;”<sup>a</sup> and the old bone within will frequently rattle,—like the kernel of a dry nut. The old bone is called “sequestrum.”

*Exfoliation.*—If it be not a long bone which is dead, but merely a plate, or a flat bone, this is separated by ulceration. Granulations form under the old bone, and push it off. This process is designated “exfoliation;” because the bone comes off like a leaf (*folium*).

These are the “terminations,” as they are called, of inflammation; but I should rather say they are the *effects* of inflammation, than *terminations*; because inflammation does not necessarily terminate when they occur. Inflammation frequently goes on after these effects take place; and therefore we ought to say, strictly speaking, that these are the *effects* of inflammation, or circumstances that occur from inflammation.

*Induration and Softening.*—Some authors mention “scirrhus” among the terminations of inflammation; but if they mean the scirrhus which afterwards becomes cancer, they are certainly wrong; because scirrhus will occur without marks of inflammation. A part, without these marks, will gradually become cancerous. It seems to be a specific disease. If, however, by “scirrhus,” these writers mean *true* scirrhus,—mere induration, then they may be right; because one of the effects of inflammation is to harden. When a part has been inflamed for a length of time, it frequently becomes indurated; so that scirrhus, in that sense, may be said to be the *effect* of inflammation, but not a *termination* of it; because the inflammation will go on, and the part become more and more indurated. Induration, however, is only one of such effects of inflammation as they ought to enumerate; for it has as great a tendency to cause parts to become softened, as hardened. Induration is rather the effect of chronic inflammation; while acute inflammation rather produces softening.

*Hypertrophy and Atrophy.*—Inflammation, when it continues, will sometimes cause an enlargement of parts. It will cause them to increase,—to be over-nourished; and then the occurrence is termed “hypertrophy;”—excessive nourishment. On the other hand, it will sometimes cause them to waste,—to be under-nourished, if I may so speak; and then it is called “atrophy.” It will occasion them to be indurated, or to be softened; and it will give rise to various transformations; so that a part shall become pretty firm cartilage, or even actual bone. These results of inflammation are sometimes combined in the same part; so that a part may be both hypertrophied and atrophied. If a part be compounded of different structures, one structure may increase,—become harder, and thicker than before; while another constituent of the same organ wastes away; and one part may become indurated, while another shall become softened. Hypertrophy and atrophy, or induration and softening, in different structures of the same compound organ, may therefore co-exist. A thickening of the *investing membrane* of an organ, for example, and a wasting of the *substance* of the organ itself, are met with. The retina is sometimes found in a state of atrophy, while other portions of the eye are excessively thick, or indurated to the consistence of cartilage. Acute inflammation

<sup>a</sup> From *nekros*, to destroy.

more frequently, as I have already said, causes softening than hardening; and wasting rather follows acute inflammation than chronic; except when the chronic form induces such over-nourishment of one constituent part of an organ, that another structure wastes. Generally, however, acute inflammation is disposed to produce softening; and if any other change occur, it is rather that of atrophy. Chronic inflammation, on the other hand, chiefly causes parts to become hard, and hypertrophied,—over-nourished,—thickened; and it is this which causes transformations,—causes parts to become cartilage or bone. I do not mean to say that these changes will not arise without inflammation; but when they are produced by inflammation, it is usually the chronic, and not the acute form, which gives rise to them.

*Changes without Inflammation.*—It is to be remembered, that these various changes of size (hypertrophy and atrophy), and of consistency (induration and softening); as also these transformations; the occurrence of hæmorrhage; the occurrence of dropsical effusion; the occurrence of a discharge from a mucous membrane (a gleet); and perhaps adhesion, ulceration, and mortification;—may all take place without any inflammation. They are continually the effect of inflammation; but certainly most of them do sometimes occur, without our being able to discover that any inflammation existed. In the case of hæmorrhage, though it is frequently the result of an active inflammation, and generally, too, in a mucous membrane, yet it is often passive; and is poured forth without either pain, heat, swelling, or general irritation;—nay, it is frequently poured forth without any fullness discoverable in the vessels of the part. I have opened persons who have died from hæmorrhage, in whom there was no collection of blood to be found in the parts which afforded the hæmorrhage. While every part of the body, from head to foot, was perfectly pale, there was hæmorrhage from time to time, until death ensued; and it must have come from small vessels, because no large vessels could be discovered to be ruptured. Chronic hydrothorax and ascites certainly do sometimes occur without any inflammation of the serous membranes;—no pleuritis,—no peritonitis. With respect to mucous membranes, a gleet frequently exists, without the occurrence of any one symptom of inflammation. It is even thought by some, that suppuration of the lungs will take place without inflammation;—that where a single vomica of mere tubercular matter has been generated, and suppuration has taken place, there has often been no previous inflammation. It is certain that large adhesions continually occur in the pleura, in persons who have no recollection of having been the subjects of inflammation within the chest. Occasionally portions of fibrin are spit up from the bronchial tubes, without a person having, beforehand, suspected the slightest inflammatory state of those parts. Ulceration is thought, by some surgeons, occasionally to occur, without inflammation, in the cartilages of joints, and ulceration will certainly now and then take place in the skin and throat, with little or no inflammation. Such ulceration is continually seen in scurvy. Ulcerated, like softened, mucous membranes, are sometimes quite pale. Mortification frequently occurs without inflammation. Instances of this are seen in the lungs; and more rarely in other viscera.

*Ligature.*—When the chief vessel of a part is obstructed by a ligature, this will frequently produce mortification of those parts below, to which the ramifications of the obstructed blood-vessel are distributed.

*Diseased Grain.*—Spurred rye, or “ergot of rye,” causes mortification, I believe, in all animals; though the quantity requisite for that purpose varies in different species. If an animal live upon it, there is sometimes a reddish fluid observed to ooze from the nostrils; sometimes there is violent pain of the extremities; and sometimes there is also heat and redness,—actual inflammation; and then gangrene takes place. Frequently, however, it does not cause heat and redness, but a withering of the part; which will dry, and look like the extremities of a mummy. The extremities become cold, dry, and shrivelled; and, at the same time, diarrhœa, vertigo, convulsions, and delirium, very frequently take place.

Internal inflammation is frequently induced in the alimentary canal; but the extremities generally mortify, and present the appearance which I have described. It is common in France, and formerly prevailed in England; the cause of which appeared to be the consumption of diseased wheat. Sometimes the legs will mortify from bad food; and the most common kind which produces this effect, is diseased grain.

I believe that other grain, diseased in a similar manner, has a similar effect. The ergot of maize in Colombia, is said to act in the same way. At least, it will cause the hair to fall off,—sometimes the teeth to drop out; and it frequently induces sudden death. It so happens that brutes are exceedingly fond of it. They will therefore frequently gorge themselves with it, and then die suddenly. It was observed that the hens which ate of it, in Colombia, discharged their eggs prematurely,—before the shell was formed; and it is *thought* that the fact of its occasioning the abortion of eggs in hens, led persons to employ it in the case of the human subject, for the purpose of emptying the uterus speedily. Its peculiar properties appear to be destroyed by cold; for it is found, that if this diseased maize be carried over cold mountains,—over the Paramos, it may afterwards be eaten with impunity.

*Gangrene from Ossification of the Blood-Vessels.*—Mortification will sometimes occur, not from inflammation, but more probably from ossification of the minute arteries. Some say that mortification will arise from the ossification of the larger and more distant arteries; but certainly it is generally believed to be sometimes occasioned by the ossification of the minute arteries. Cruveilhier, by artificially inducing a similarly obstructed state, produced the same effect. He injected mercury into the arteries, so as to fill the capillary vessels with it; and when an obstruction was thus produced, mortification was the consequence.

*Dry Gangrene.*—The mortification which arises from obstruction in the vessels, induced by ossification of the minute arteries, most frequently takes place in males; and especially in the old and voluptuous. Generally the gangrene is dry,—the part shrivels up; and this state is preceded by very great pain. There are two varieties of dry gangrene;—the *pale* and the *black*. Mortification may occur without inflammation. Many things, however, are asserted, in medicine, without sufficient proof; and occasion a great deal of trouble to those who follow the asserters, by making it necessary for them to prove that the assertions are not true. This circumstance, in medical writings, is too common an occurrence. I do not know that it is proved, that mortification is always preceded or accompanied by inflammation; but if it be, the mortification is often not proportionate to the inflammation. The severest mortification may be seen with the slightest inflammation, or with its entire absence; and, on the contrary, the most intense inflammation, without inducing mortification. Some inflammations have a peculiar tendency to end in mortification. The inflammation of glanders, in the human subject, though not more intense than many other inflammations of the face, has nevertheless a great tendency to induce mortification.

*Changes from Inflammation.*—With respect, then, to all the effects of inflammation, and those changes which, though they frequently are its effects, yet sometimes appear not to be exactly so,—I may mention that induration is generally the result of slow inflammation; but that softening is continually seen without any signs of inflammation at all. Hypertrophy (over-nourishment), like induration, is, I believe, generally the result of slow inflammation; but atrophy, the wasting of a part, is frequently seen without inflammation. In phthisis, the heart is usually small, flabby and perhaps shrivelled; though not previously inflamed. The transformations of one structure into another structure, natural to the body, though not to the individual part, and therefore called “analogous” formations, are certainly more frequently the result of inflammation than otherwise; but the new formations—those which are not analogous to any thing already existing in the body—are far more frequently not the result of inflammation. It continually happens that there is not a vestige of inflammation to be found during their production. They appear

to be alterations of action, rather than the result of an actual inflammation. The part is entirely altered, and a new product is formed. When inflammation does accompany those new formations which are called "*non-analogous*," such as encephaloid disease, or cancer, it is often only an accompaniment, and not their cause. Sometimes it is only the *predisposing* cause. Inflammation throws a part into a predisposition to disease; and then a fresh disease is set up. That these things are not the result, at any rate, of mere inflammation, is shown by the fact, that more inflammation continually occurs, without such effects being induced. In these affections, although we may employ the most vigorous antiphlogistic measures, in the most persevering manner, the disease may resist; we scarcely control it, or not at all. The tendency to the morbid process is continued; and the disposition to it would often appear to excite the inflammation:—that is, the inflammation appears to be the consequence of the disposition to the disease; and not the disposition to be the result of the inflammation. Indeed, inflammation, in many cases, is only the ultimate effect. The new formations irritate the part so much, that inflammation is excited, and an attempt is made by nature to discharge the formation. In this way scirrhus has sometimes been completely separated, by nature, from the body.

*Tubercles.*—The existence, in the lungs, of tubercles, (which are new formations, not analogous to any thing in the body,) cannot be the result of mere inflammation; because inflammation occurs every day without them; and they, too, are often produced without signs of inflammation.\* Occasionally, people who are disposed to this disease will, by having the lungs thrown into an unhealthy state by inflammation, become the subjects of tubercles from that time; because any thing which throws the body out of health, gives a predisposition to disease of some kind or other; or if there be a predisposition, it is increased, and the new disease is excited. If a rabbit be badly fed, and kept in a damp place, and in the dark,—so that it has a deficient quantity of light and heat, together with unwholesome food,—it may become the subject of tubercles. A new, depraved secretion takes place; which, however, is not the result of inflammation. If we gave stimulants to an animal, we might produce an inflammatory state of the whole body, or of any organ; but should not induce tubercles. The attempt to explain every thing by inflammation, appears to me an absurdity; and I am happy to find that my opinions on this subject coincide with those of Andral and Louis; who argue successfully, that inflammation is not always the cause of tubercles; that they occur continually without inflammation; and that when they do occur as the consequence of inflammation, it is not so much the result of the inflammation itself, as of the part being thrown out of health, and thus easily becoming the victim of the predisposition to tubercles. These are all the observations that I have thought it necessary to make, respecting the symptoms and effects of inflammation. I shall hereafter speak of changes of structure in general.

Such are the usual phenomena of inflammation. Such are the chief symptoms; such are the general effects or terminations; and such is its course. The next point which I shall consider, is the variety in all these respects, occasioned by the nature of the structure which it attacks. The varieties induced in inflammation by the structure affected were first considered by Dr. Carmichael Smith; who published (in the second volume of the "*Medical Communications*," printed in 1788) a very admirable and classical paper on this subject. His attention, however, was confined to inflammation. Nearly ten years after this, Pinel, a celebrated French physician, adopted this same arrangement; and he, I believe, generally has the credit upon the continent; while our countryman is overlooked. Bichat, in his "*General Anatomy*," afterwards pointed out that *all* diseases might be considered according to the structure which they affect.

\* This view is confirmed by the recent important pathological researches of M. Louis.

## SECTION VI.—VARIETIES OF INFLAMMATION.

There are five chief structures, which Dr. Carmichael Smith considered as giving rise to the most decided varieties in the symptoms of inflammation. These are the skin, the mucous membranes, the serous membranes, the cellular membrane (including the substance of the organs), and (according to him) the muscles; but we ought rather, perhaps, to say the fibrous membranes; such as ligaments and aponeuroses, tendons, and the periosteum.

*Inflammation of the Skin.*—When the part inflamed is the skin, it exhibits an intense shining redness, which is instantly removed by the pressure of the finger; and as instantly returns, or nearly so, when the finger is removed;—so that the skin is made white by pressure; but almost as soon as the finger is removed, a blush pervades the part, which becomes as red as before. If this inflammation of the skin be of a simple character, and in a patch,—if there be nothing more than the inflammation of the part, the term given to it is “erythema.” It is not every inflammation which is erythema;<sup>a</sup> but the simplest patch of inflammation on the skin is so designated.

The character of the pain, when the skin is inflamed, is burning and smarting; and when the inflammation subsides, it is frequently followed by the separation of the cuticle in branny particles, or scales, or even large shreds. This process is called “desquamation.”<sup>b</sup>

Very frequently, when the skin is inflamed, vesicles of various sizes appear; and, not unfrequently, there is a very great effusion of serum into the subjacent cellular membrane; so that where the skin is inflamed, the whole part becomes swollen, puffy, and œdematous. As the skin is a continuous surface, every inflammation of it which is entirely superficial, has a great tendency to spread; and sometimes, when that takes place, the part first affected recovers itself; so that the disease appears to wander along the body, like a cloud;—forsaking one part, and going to another. But, on the other hand, we sometimes have the part originally inflamed still affected;—the disease having merely extended itself still farther. Sometimes the inflammation does not spread in this way, but dips down; so that the cellular membrane below is not merely filled with serum, but becomes the subject of actual inflammation. If this occur in mere points, matter may be formed; and what are called “pustules,”—which consist of a number of little minute collections of pus. Sometimes they may be formed, indeed, without the cellular membrane being affected; the surface of the skin alone being attacked; but frequently the pustules extend through the skin, deeply into the cellular membrane. Sometimes, moreover, a frightfully extensive inflammation of the cellular membrane takes place;—suppuration being very likely to occur; and then the disease is designated “erysipelas phlegmonoides,” by some called “diffused inflammation of the cellular membrane.” The skin, therefore, may be inflamed superficially, and remain so; or the inflammation may dip down into the cellular membrane below; and then all the characters of inflammation of the cellular membrane, in addition to those of inflammation of the skin, appear. This may be considered a complicated disease;—an inflammation of two parts.

*Inflammation of Mucous Membrane.*—The second structure which gives variety to inflammation, is mucous membrane. Mucous membranes are very nearly allied in structure, as well as in all other qualities, to the skin. In Bichat’s beautiful “Treatise on Membranes,” the analogy is pointed out between mucous membranes and the skin. It is a work well deserving of study. Heule, however, has recently published some important researches on the intimate organization of membranes. He has shown that the epithelium, which is the proper cuticle of mucous membranes, consists of vesicles flattened and disposed in a tessellated manner. When a mucous membrane is inflamed, it becomes thicker than usual; its temperature in-

<sup>a</sup> From *ερυθρος*, red.

<sup>b</sup> From “desquamo,” to scale off.

creases; and it becomes tender to the touch. The pain which is experienced is dull and diffuse, though sometimes it is of a pricking character; but if not pricking, it is obtuse and diffused. When the inflammation first begins, the secretion of the part is increased. It is, however, watery, or thin; and perhaps acrid. This any one may observe in a common catarrh. When a cold begins in the Schneiderian membrane of a nostril, the nose "runs," as it is called. The secretion is increased, but is not at first very excessive; nor is it thick, but thin; frequently, however, it is more or less acrid. As the disease advances, the discharge becomes, perhaps, entirely suppressed; but, as the disease declines, the secretion increases again,—becomes excessively copious and viscid,—perhaps offensive; and then, again, it gradually lessens. If the inflammation be not intense, the secretion remains mucous; although it may be altered in its quality,—may be diseased, still it is mucous. If, however, the inflammation be more intense, the secretion becomes puriform; and a still higher degree of intensity will give rise to absolute pus,—purulent discharge. All this is observed in inflammation of the urethra; where inflammation is far more violent than that which occurs in the nose. The inflammation of catarrh generally produces nothing more than mucus; but the inflammation of severe gonorrhœa is so violent, as to cause the formation of pus. If, however, the inflammation be still more violent than that which occurs in purulent gonorrhœa, you may not simply have pus produced, albumino-fibrin will be poured out. One of the most violent inflammations of a mucous membrane, is the croup of children; in which disease, the mucous membrane pours forth a plastic fluid; by which the parts become obstructed, and a tube of new secretion is produced. I have seen the same occur in the urethra; where an individual, in consequence of a violent gonorrhœa, has used strong injections, the result of which was the excitement of a dreadful inflammation. Pus had been secreted before, but now adhesive matter; a portion of which, exactly resembling an earth-worm in appearance, except in colour, was discharged from the urethra.

Occasionally, when mucous membranes are inflamed, hæmorrhage takes place from them. They become so overloaded with blood, that the vessels allow its escape, and hæmorrhage ensues. This is more particularly the case with inflammation of the mucous membrane of the intestines, and of the urethra. Now and then ulceration and mortification occur; this circumstance generally happens, however, in the throat and intestines. It often takes place from the very beginning; and is not at all in proportion to the degree of inflammation. There often appears to be a strong disposition to ulceration. Inflammation of a mucous membrane frequently degenerates into a state of chronic discharge; so that when the inflammation is over, the part continues to pour forth a quantity of fluid, without pain and without heat. This particularly occurs when a mucous membrane has been inflamed several times; and we especially notice this gleet, as it is termed, from the bronchi and the urethra. The latter is every day seen in young men; and the former in those who are old. Hence we have "catarrhus senilis,"—a gleet,—a constant discharge from the mucous membrane of the air-passages, without any inflammation.

If we examine these membranes after death, when they have been inflamed, we find them thicker and softer than natural. If the inflammation should have continued very long, they will frequently become very soft and thin; but, on the other hand, just the reverse is frequently observed. If inflammation have induced softening, they may be rubbed off by the finger, from the cellular membrane beneath. Sometimes, however, these mucous membranes become indurated. If we find a mucous membrane soft,—as we frequently do in the case of the stomach,—it is no proof that it has been inflamed. I believe that a part will occasionally become softened, without any inflammation;—at any rate, I know that the softening is frequently out of proportion to any inflammation that has existed. Generally, when a mucous membrane has suffered acute inflammation, it is found to be thicker and softer than natural. It is much more rare to find it hardened. The usual effect of acute inflammation, is to soften parts; but if it should occasion a considerable deposition of albumino-fibrin, and that be retained in the cells long enough to coagulate,

it will cause an appearance of induration. Baron Dupuytren, the eminent French surgeon, and Dr. Thomson, of Edinburgh, found inflamed arteries softened; and the stomach, bronchia, and heart, when inflamed, are continually found soft. This is the more general effect, therefore, of acute inflammation of mucous membranes.

[The softening which follows inflammation, may be appropriately considered of two kinds—that which immediately succeeds an attack of acute inflammation, and depends upon the effusion of liquor sanguinis in the cells of the structure in which the action occurs—and that intimate change in the organization of a part, which supervenes at a more remote period after the accession of disease. This latter state, unlike the former (which is mechanical), is caused by perverted nutrition, and is vital; for the softening is an organic process, and does not depend upon the solvent power of the fluid effused into the cells. If the more serous portions of the contents of the tissue were taken up by absorption, and the remaining fibrinous parts to undergo coagulation, it is evident that the opposite state of *induration* would result. It is necessary, however, to distinguish this from another species of *hardening*, which is due to hypertrophy, or excessive nutrition.—*T. Williams.*]

Sometimes, when a mucous membrane has been severely inflamed, it is almost black. Through the mere congestion of blood, it will look dark, as if it were mortified; but, on handling it, it is not found lacerable, like a mortified part; but still rather firm and solid, and devoid of fœtor. Great mistakes have been continually made in the inspection of bodies. After inflammation of the intestines, we often find portions of them nearly black, without any particle of mortification; and frequently such cases have been pronounced, at once, to be mortification of the intestines. Mere congestion of blood will make a mucous membrane almost black; as is seen in the case of the genital organs of rabbits during heat. The error to which I have alluded, is pointed out by Dr. Baillie, in his “Morbid Anatomy.”\*

It is a general remark that the feverishness,—the *pyrexia* attending the inflammation of a mucous membrane, is comparatively mild, and the tolerance of the loss of blood is low. The pulse is generally soft, although quickened; and the more frequent the attacks of inflammation, in any individual mucous membrane, the more mild they are, and the more early and profuse is the discharge.

*Serous Membranes.*—If the part inflamed be a *serous* membrane,—such as the arachnoid, the pleura, the pericardium, the peritoneum, or the tunica vaginalis,—the pain is for the most part acute,—darting,—lancinating. The pulse is not soft, as in the case of inflammation of a mucous membrane, but is generally hard, though by no means always. It is a general, but not a *universal* remark, that the pulse is hard. The inflammation causes here a copious effusion of serum, with fibrin in solution. This fluid is sometimes limpid, clear, and of a lemon-colour; but is generally turbid; except, perhaps, in inflammation of the head. The serous collection is generally of a yellowish colour, like whey; and sometimes it is puriform;—the fluid, in many portions, resembling pus; although other portions of it may be more like serum. Sometimes, however, absolute pus is produced; so that the pericardium has been filled with this fluid. Sometimes it forms a jelly-like yellowish mass; sometimes minute shreds or flakes are seen swimming about the fluid; and sometimes it forms regular layers, resembling skin. These deposits of fibrin will at length grow vascular; and, when vascular, they will adhere to the surrounding serous membrane; and at last become thin again, and in all respects resemble cellular membrane. Hence they have been frequently called “false membranes.” A false membrane is, originally, nothing more than an effusion of liquor sanguinis; which has become organized, and adherent to the surrounding serous membrane from which it has been poured forth; and has then become, in all respects, like cellular membrane.

\* There is no difficulty, however, in distinguishing between this congested condition of a part, and the state of positive mortification. When congestion only exists, the proper organization of the part continues, and its strength is such as to resist the pressure of the finger; but in mortification the natural structure is lost, and the slightest force breaks down the part.—*T. Williams.*

This deposit is distinguishable into two portions;—one solid, and the other fluid. The solid is fibrin itself; but within the various portions of the solid mass, between the layers and cells, is found a fluid which is albuminous. When these depositions have become adherent, they may be injected from the surrounding parts; but,—as a coagulum of blood has been seen to have vessels of its own, although such vessels are formed from the influence of, and connected with, those which surround them,—so will these depositions of fibrin, before they are visibly adherent to the surrounding serous membrane, become vascular. Within these products, there has even been found a puriform fluid, while they were still unconnected with the surrounding parts. Andral says, that he has distinctly found a fibrinous concretion, unconnected with the surrounding parts, swimming in liquid in a serous cavity; and frequently, even in this concretion, he has found pus. It is said that the circulation within these parts is of three kinds. When they are first formed, currents take place in the interstices, through irregular areolæ; in the next place, insulated vessels are found; and thirdly, these vessels at last become continuous with those of the neighbouring parts. Andral says, that each of these stages may exist in different parts of the same fibrin. The opinion entertained by recent pathologists is, that although these concretions may form before death, they cannot become organized unless attached to the sides of the heart or vessel.

When a serous membrane which has been inflamed is opened, some points, stars, or patches of vascular redness are found. In the first degree of inflammation there are merely points; if there be still more inflammation, there are stars; but if there be a still higher degree, and very numerous vessels contain blood, then a diffused redness appears.

*Parenchymatous Structures.*—When the part inflamed is either the cellular membrane, or the substance of organs, as the liver, the pain is fixed;—not diffused, as in the case of a mucous membrane; but fixed and rather acute, though not so acute as in an inflamed serous membrane. It is rather dull, but rather acute, notwithstanding; and even pulsating, or throbbing. There is an effusion of serum into the surrounding parts, and at length suppuration takes place in that spot where the inflammation is most intense; and in the midst of the effusion an abscess is formed. If any tumour be produced, it is hard; and it becomes soft when suppuration commences,—the pain remitting at the same time; though, generally, the tension, from the collection of matter, keeps up the pain and the other symptoms. When the matter escapes, the part heals by granulation and cicatrization;—as I mentioned when speaking of abscesses.\*

Inflammation of the substance of the viscera, or of any part of the cellular membrane, forming an abscess, rarely ends in gangrene; except that particular form which is called “carbuncle.” The inflammation of the cellular membrane, or substance of the viscera, is called “phlegmon.” When, however, it is near the surface, and has a tendency to produce gangrene, it loses that name, and we call it “carbuncle.” In the latter, the cellular membrane will die to such an extent, that surgical aid is necessary, to make large openings for its escape;—in order that its spread may be arrested.

Inflammation of the cellular membrane, and of the viscera, is sometimes not insulated, but diffused; and (as was remarked, when speaking of the skin<sup>b</sup>) this is frequently called “erysipelas phlegmonoides,”—provided the skin be also inflamed; or “diffused inflammation of the cellular membrane,” if the skin be not inflamed. This inflammation is occasionally chronic. Nothing is more common than for inflammation of a *mucous* membrane to be chronic; but inflammation of a *cellular* membrane is not so frequently chronic, though sometimes it is; and we observe this especially in the lungs and liver; so that people labour under chronic pneumonia, and more frequently under chronic hepatitis.

*Fibrous Membranes.*—Fibrous membranes include fascia, aponeurosis, tendons and their sheaths, ligaments, the sclerotic tunics, and periosteum. If these be

\* See Page 98.

<sup>b</sup> See Page 106.

inflamed, the disease which commonly exists is rheumatism. There may, however, be inflammation of any of these parts without rheumatism; but if there be a general tendency to inflammation of these throughout the body, it is called "rheumatism." Frequently, however, the inflammation of a single one of these parts is the same disease. In rheumatism, although the pain is obtuse, yet there is a feeling of tension; and gelatinous exudations, analogous to synovia, take place. This form of inflammation rarely runs on to suppuration; still more rarely, if ever, to mortification. The pyrexia may be out of all proportion to the violence of the local inflammation; and, indeed, one character of the disease is the occurrence of profuse sweating. In acute rheumatism, profuse sweating is seldom absent, at some period of the disease. It generally occurs at the commencement of the affection. At any rate, if the patient be kept at all warm, the tendency to it is sure to show itself; and the sweats are frequently of so marked a character, that we can be at no loss instantly to discover their nature. They are usually very sour. This variety of inflammation generally terminates in resolution, or degenerates into the chronic form;—perhaps with a chronic collection of gelatinous matter about the joints, and in the thecæ of tendons.

The peculiarity of this inflammation, is its great tendency to wander,—to *migrate*; so that it is now in one joint, and in a few hours in another. Occasionally it is metastatic; it will cease in these particular parts, and inflammation of an internal part will begin;—generally an inflammation of some membrane; either the arachnoid, I believe, or the dura mater;—we cannot say exactly which; but, certainly, more frequently than not it is the pleura or the pericardium;—the latter, however, more frequently than any other. But it is not by metastasis only, that this internal inflammation takes place; for inflammation of the pericardium or of the pleura, occurring in rheumatism, is continually brought under our notice, while the affection is going on in the joints, just as violently as before; and frequently this internal inflammation does not take place, till after the rheumatism has ceased for some time. When the pericardium, for example, has been inflamed, if the person do not die, the pericarditis has a great tendency to become chronic. Disease of the heart is then set up; the substance of the heart itself frequently becomes thickened, or hardened, or softened; the internal membrane, chiefly about the valves, becomes affected; and organic disease of the heart is soon established. This is by far the most common origin of diseased heart in young persons. It commonly begins in pericarditis, which is generally connected with rheumatism.

*Varieties from Sympathy.*—Such are the chief varieties of inflammation occasioned by *structure*. The *sympathies* of the particular part affected, likewise occasion varieties in the general symptoms. Some of the symptoms arise from the sympathies of the *general structure* affected. For example: if the structure affected be a *serous* membrane, its sympathies give rise to a peculiar pulse;—in general a hard pulse. From another sympathy, when *fibrous* membranes are affected, a particular sweating is excited. But, besides these general sympathetic effects,—which are due to a peculiarity of structure,—other sympathetic effects, depending upon the particular office of the organ, arise. If the stomach or intestines be inflamed, we generally have a sensation of great weakness, and a wiry pulse; but this does not occur as the consequence of an inflammation of the peritoneal coat of the intestines, or any other of their coats;—for then it would take place when a similar structure was inflamed in other parts; but it occurs because the organ affected is the *intestines* or *stomach*. When the kidney is inflamed, vomiting, a retraction of the testis of the same side, and various other symptoms occur; simply because the *kidney* is inflamed. Hence a certain set of symptoms is induced in inflammation, from the peculiar sympathy of other organs with the part affected.

There are other varieties also observed. Erysipelas of the head has a great tendency to run to the brain. This can hardly be called "metastasis;" because the inflammation frequently still continues violent in the face itself, even after the symptoms of phrenitis come on. Inflammation of the parotid glands, of that pecu-

liar kind said to be contagious (called "mumps"), has a great disposition to occasion sympathetic inflammation of the brain or of the testes. Indeed, when any organ is inflamed, and the inflammation continues any length of time, it is not uncommon for another and a distant organ to become inflamed likewise. This organ is generally either the brain, the lungs, or the alimentary canal;—sometimes, however, (though less frequently,) the skin, and sometimes the throat. When a part has been once inflamed, it has a great tendency to fall into inflammation again, from slight causes. We certainly have inflammation of an organ, from sympathy with the particular organ affected; and very frequently when this second inflammation occurs, although it may be very slight, it is attended with very considerable ill effects. The constitution is so much impaired by the first inflammation, that the addition of disease, though slight, in another organ, produces very great danger, and frequently death.

*Intermittent Inflammation.*—Inflammation is sometimes intermittent, and sometimes absolutely periodical. Inflammation of the eye has been observed to recur at particular periods. It has frequently been observed to be intermittent,—to come on violently every evening, or every other evening, at a certain hour. I have also seen periodical catarrh.

*General Health.*—There are variations of inflammation, according as the constitution is healthy or unhealthy. If the constitution be healthy, the inflammation is more active,—is more rapid; and the terminations, when they occur, are more perfect. When the constitution is in an unhealthy state, the parts inflamed are feeble. There is less activity in the inflammation, less brightness of colour. The terminations which take place are less perfect; and the secretions of the part are more unhealthy.

*Specific Inflammation.*—There are other varieties in the symptoms of inflammation, depending on the cause which has produced it; and the inflammation on this account is frequently termed "specific." For example: inflammation of the skin, as in small-pox, is induced by a specific cause; and therefore it is called "a specific inflammation." Independently of the cause, some inflammations run a peculiar course, and are therefore specific. Such is erysipelas.

*Passive Inflammation.*—I have hitherto been considering *active* inflammation; but inflammation is sometimes also said to be *passive*. If, in inflammation, there be but little pain; if the redness be dull; if the heat be but slightly increased, perhaps not at all; if there be more than the usual swelling, and a very abundant secretion;—in this case the inflammation is said to be "passive." I have already mentioned,<sup>a</sup> that some persons object to this term; and say that such a set of symptoms as these are not inflammation; and Andral, to avoid the difficulty, calls all inflammations and congestions "hyperemy,"—the excessive presence of blood in the part. "Active *hyperemy*" is synonymous with "active *inflammation*;" whereas, if the symptoms be those I have just described,—a dingy colour, flaccidity of the parts, and little or no pain,—then, instead of calling it "passive *inflammation*," which he says is absurd, he calls it "passive *hyperemy*."

*Acute and Chronic.*—These terms apply merely to the *duration* of inflammation; and not to the difference whether it is active or passive. An *acute* inflammation may be *passive* from the first. When a person is already weak before the attack of inflammation, or the part has been frequently inflamed before, then at the very outset the inflammation may be of a passive character, although acute. After inflammation has continued for a length of time, it may be still active;—the part may still be hot and painful, and this state may yield only to the remedies of active inflammation. Hence "*active*" and "*passive*," with respect to inflammation, as well as all other diseases, are not synonymous terms with "*acute*" and "*chronic*."<sup>b</sup>

*Tonic and Atonic.*—Inflammation is sometimes distinguished into *tonic* and *atonic*; and these terms refer, not to the active or passive condition of the part,

<sup>a</sup> See Page 77.

<sup>b</sup> See Page 37.

but the powers of the system. If the constitution be strong, the inflammation is called "tonic;" whereas, if the system be in a weak state, the inflammation is called "atonic;"—because inflammation is sometimes very violent in the part, and yet there is no power in the system. The activity is all of short duration; the powers are exhausted; and perhaps mortification takes place. The activity,—the violence of inflammation in a part, is more than commensurate with the powers of the system. If the *part* be in a state of activity, the inflammation is called "active;" but if not, it is called "passive;" whereas, the words "*tonic*" and "*atonic*" refer rather to the powers of the system at large.

## SECTION VII.—CAUSES OF INFLAMMATION.

*Predisposing Causes.*—I shall now consider the *causes* of inflammation; commencing with the *remote*; and of the remote causes, the *predisposing*, of course, come first to be considered. The circumstance which primarily predisposes to inflammation, is the sanguineous temperament; and the next may be considered high health. In the sanguineous temperament, there is generally a great quantity of blood;—at any rate, there is a large quantity in the minute vessels; so that the blood—the pure blood itself—circulates to a great extent throughout. The body is readily flushed; vessels, which should not, readily receive blood; and the circulation is full and rapid. I need not say, that high health must have the same effect. A person in a high state of health, has a florid colour. There is an increased quantity of blood circulating throughout the body, and to a greater extent than in other temperaments. Besides these two general circumstances of the body, the same occurrence may take place locally. There may be a local sanguineous fulness,—a local fulness of blood; and that may predispose a part to inflammation. The face is certainly more supplied with blood, than any other portion of the surface of the body; and consequently when exanthematic affections (such as measles and small-pox) take place, most of them affect the face, sooner than any other part of the surface; and the inflammation which occurs there is severer. The same thing will occur from a particular period of life. In children, the circulation appears most vigorous in the head. What is called "determination of blood to the head" takes place;—all that is meant by which term being, that more blood (proportionately) is circulating there than in other parts. In youth, the greatest determination is towards the chest; and in the middle period of life and afterwards, it is in the abdomen. Hence children are particularly disposed to hydrocephalus,—to inflammation of the arachnoid membrane of the brain,—to other cerebral affections; and are continually having fits,—continually having affections of the head; and, consequently, a large number of children die of acute diseases of the head. Hence, too, children are particularly subject to epistaxis. Persons in youth—those who have passed the period of childhood—are certainly more subject to all affections of the chest,—to all thoracic inflammations, and to inflammatory spitting of blood. It is adults, particularly, who have inflammation of the stomach and intestines, both acute and chronic;—especially chronic inflammation of the stomach and of the liver;—indeed, inflammation, and congestion, and structural changes of all the abdominal organs.

Seasons and climates will operate in the same way, by exciting either general or local fulness. Pulmonary inflammation is more common in cold climates, and likewise in the winter and spring; whereas in hot climates, and in the autumnal season of temperate climates, hepatic inflammation is most common.

Occasionally a part will acquire an increased excitability from a previous injury; and this is remarkably shown in the head. If a person have once had a severe injury of the head, he may afterwards suffer from a slight cause;—a cause which scarcely would have disturbed him before. I saw a person who had had a fracture of the skull; and, for many years afterwards, he would become completely delirious, on taking a glass of spirits. This is an occurrence, indeed, that

I have frequently seen. I very well recollect the case of a man, who laboured under rheumatism of different parts of the body, and among others of the scalp; but he had suffered severe fracture of the skull some years before; and the mere excitement of the external part of the head, was sufficient to excite it internally; so that he had violent delirium from mere trifling rheumatism of the scalp.

Previous inflammation from any cause, disposes a part to be inflamed again. Various causes, of an opposite tendency, will also have the same effect. Bad air, copious evacuations, bad food, depression of mind, fatigue of body, fatigue of mind, the frequent exhibition of mercury, an exhausting climate, and previous disease of any kind, will also dispose to inflammation. While all these predisposing causes, however, induce inflammation, its character differs totally according to the nature of the cause. The inflammation induced by the first kind of causes I mentioned, is active and tonic; whereas the inflammation predisposed to by bad food, bad air, depression of mind, and so on, is either passive or atonic;—the inflammation itself is of a passive character; or there is not sufficient power in the system to carry it on,—to get the patient well through it, or to produce a healthy secretion of pus, if pus be produced. Hence the character of the inflammation varies, according as the predisposing cause is one which gives strength, high health, and excitement; or one which destroys health and strength, and gives a tendency only to an unhealthy excitement.

Some of these latter causes, such as the defect of heat and of food, act as predisposing causes to inflammation, without producing any debility, or any atonic character of inflammation. If a part be exposed to cold, it becomes more affected afterwards by a given degree of heat. If a person be deprived of food, and then a small quantity of food, though of the weakest character, be given him, it will produce an excitement which only strong food and a large quantity would have produced before; and therefore some of these predisposing causes may act, also, by rendering the part more liable to be affected by stimulants; for stimulants act according to circumstances that went before them. According to the first, so is the second; and all that is requisite is, that there should be a great disproportion between the two. It is no matter whether the first is very defective, or the second is very great; for the effect is in proportion to their *relative* intensity; and therefore parts which have been exposed to cold, become violently inflamed if exposed to a moderate heat; and a person who has been nearly starved previously, has been known to become delirious, on taking merely a little veal-broth. Many of these causes, however, produce a cachectic<sup>a</sup> state of the constitution; and then inflammation, if it occur, is of a corresponding character.

*Exciting Causes.*—With respect to the *exciting* causes, we may mention, in the first place, a local stimulus;—be that stimulus mechanical, or chemical, or what is *properly* called “a stimulus;”—a stimulus independent of mechanical or chemical qualities; such as alcohol. The effect of all stimuli (as I have just now said) is not dependent upon their positive degree of force; but upon the difference between these stimuli, and the strength of those which preceded them. Every body knows the danger of going from cold to intense heat.

*Cold.*—Besides local stimuli, whether mechanical, chemical, or true stimulants, the depression of stimulation in one part, will cause an inflammation in another. From having the excitement in the feet exceedingly depressed,—by getting wet through, and sitting with wet shoes,—there will be such increased activity at a distant part, that inflammation may occur; so that many persons always have a sore throat, or inflammation of the chest or eyes, if they get wet through, or have wet feet. This application of cold—depressing the action of one part, and thus producing an excitement in another—depends very much for its effect upon the previous excitement. If the feet, for example, have been already hot;—if they have been heated, and are in a state of perspiration,—then the application of cold produces so great a depression, that the inflammation of the throat (for example) or

<sup>a</sup> From κακος, *bad*; and εἶς, *a habit*.

the lungs, will be so much the greater. The more partially cold is applied, the more injurious (within certain limits) is it found to be in producing distant inflammation; but cold will itself, I believe, directly induce inflammation;—exactly as great heat will do. When we are exposed to cold air,—when exceedingly cold air is passing through the nostrils, the nose will “run;” and it has been found, by microscopic observation, that cold, like a positive stimulus (such as heat), will induce that condition of the capillaries which was formerly defined as essentially constituting inflammation;<sup>a</sup> namely, stagnation of the blood, and effusion of the liquor sanguinis. Nothing is more common than for rheumatism to be felt in the shoulders, or for an inflammatory pain to be felt in the ear, when cold air is blowing upon these parts; although unquestionably, for the most part, these affections are of a nervous, and not an inflammatory character.

Thus it appears, that cold may induce inflammation in three ways:—1. By rendering the body liable to be very much excited by the stimuli that come afterwards;—by depressing the action so much, that when the stimulus of increased temperature is applied, the effect of this is tenfold increased. 2. By depressing the action in one part, and thus exciting a correspondent excess of action in another. 3. By exciting inflammation immediately and directly. There are many instances to illustrate these three modes of operation. First, when a person passes from the cold into a warm room, his face will become very red and hot; and frequently he will cough violently, and a catarrh will be set up. In the next place, we see persons have inflammation of the eyes, nose, mouth, throat, or chest, from wet and cold feet. And, thirdly, we continually observe pain in the ear, rheumatism of the shoulders, and the nose “running,” when cold air is applied to these parts.

I believe that sudden refrigeration, and the sudden application of cold after excitement, are more frequent causes of inflammation, than the application of heat after cold. Most of the cases of inflammation met with, are those in which persons have become suddenly cool, when they were overheated and fatigued. Perhaps, likewise, wet may have been added to this; or they may have been exposed to the influence merely of cold air. A rigor is frequently induced; and a state arises which is soon followed by inflammation. The effect of sudden refrigeration, therefore, is greater in proportion to the previous excitement: it is also greater if it be partial than if it be general; and it is always greatest if there be much sweating and exhaustion. Sometimes, indeed, fatal results have instantly occurred. Many persons, from taking ice when they have been not only hot, but sweating and exhausted, have at once fallen dead. The account of Alexander the Great bathing in the Cydnus, when exceedingly hot and exhausted, after great fatigue, is well known;—an occasion on which he nearly lost his life. How hot soever the body may be, there is comparatively little danger, if it be not fatigued. The Russians go from the vapour-bath to the snow, and roll in it.

[It has long been a popular, as well as a professional axiom, that *sudden vicissitudes* of temperature are dangerous;—that a *previous hot state of the body* augments the hurtful effect of the application of cold, either externally or internally. But the proposition, thus broadly stated, is not universally true. Sir Charles Blagden, describing some of the experiments in which he was engaged, says,—“During the whole day, we passed out of the heated room, (of which the temperature ranged from 240° to 260°,) after every experiment, immediately into the cold air without any precaution. After exposing our naked bodies to the heat, and sweating most violently, we instantly went into a cold room, and stayed there even some minutes, before we began to dress; yet no one received the least injury.” And Captain Scoresby (speaking of the Arctic regions) tells us, that he has often gone from the breakfast-room of the vessel, (where the temperature was 50° or 60°,) to the mast-head, (where it was only 10°,) without any additional clothing, except a cap;—“yet,” says he, “I never received any injury, and seldom much inconvenience from the uncommon transition.” It is plain, therefore, that the proposition

<sup>a</sup> See Page 84.

which assigns danger to sudden vicissitudes of temperature, requires limitation. The effects of a sudden descent from one point to another, in the scale of atmospheric temperature, varies according to the state of the body at the time. Without going into any physiological discussion respecting the science of animal heat, I may just remind you of the faculty of evolving heat possessed by man, and the warm-blooded animals; by which faculty very nearly the same degree of inward temperature is steadily maintained under very different degrees of outward temperature. If the external temperature be lower than that of the body, the caloric thereby carried off is speedily replaced, in a healthy adult, by this evolution of heat from within, aided by clothing, or exercise. When the external temperature approaches the standard heat of the body, sweat soon breaks forth, and the superfluous heat is removed by evaporation; for so constant is the internal evolution of caloric, that an atmosphere which does not as constantly abstract any of it, is excessively incommoding. An external temperature of  $98^{\circ}$ , which is about the average heat of the blood in man, is (as you know) extremely oppressive. The terms "hot," "warm," "cool," and "cold," as applied to the surrounding air, are regulated by the sensations that it produces upon the average of persons. If the heat be carried off as fast as it is generated, and no faster, no particular sensation is felt; and the bodily powers are neither stimulated nor exhausted. This equilibrium is maintained, (supposing that no extraordinary exertions are made,) when the thermometer stands at  $62^{\circ}$ , or thereabouts. We call that point in the scale "temperate." All degrees above that point, up to  $70^{\circ}$ , are reckoned "warm," all above  $70^{\circ}$ , "hot." Descending in the scale, we speak of the temperature denoted by any degree between the 60th and 50th, as being "cool;" and every lower degree of temperature is "cold." I am speaking of the average of healthy men; for remarkable diversities occur among individuals, with respect to the names which they assign, under the guidance of their sensations, to particular degrees of the thermometric scale;—their sensations differing according to the power which their constitutions respectively possess of evolving heat. Now, if this power of evolving heat (thus inherent in the system) be entire, and active, and persistent;—if it have not been awakened by any of those circumstances which are known to have the effect of weakening it,—no peril need attend even violent alternations of external temperature. Universal heat of the body, at the time when the cold is applied, so far from implying danger, is really the condition of safety;—provided the heat is steady and permanent. You may read, in Dr. Currie's book, numerous instances of cold affusion being employed in the hot stage of fever, and particularly in cases of scarlet fever, not only with impunity, but with great benefit to the patient. The same holds true of the application of cold, when the body has been heated by exercise; and, indeed, whatever may have been the cause of the increased heat;—provided always that that cause remains steadily in action, that there is no local disease, and that the body is not fatigued and rapidly losing its heat. But if a person be already exhausted and weakened by exercise,—if he be sweating and rapidly parting with his heat,—and especially if the exercise is remitted, and he remains at rest immediately after the application of the cold,—then it becomes highly perilous, and likely to produce internal mischief. The more correct statement, therefore, respecting the application of cold is, that it is dangerous, not when the body is *hot*, but when the body is *cooling after having been heated*.<sup>a</sup>

*Damp.*—The effect of cold applied to the body, is much increased by damp. Very often, persons do not suffer from the application of cold, till dampness is conjoined with it. It may act simply by increasing the cold,—by lowering the temperature still more; but I cannot help thinking, that it injures to a greater extent than this circumstance will explain;—that its injurious effect is out of proportion to the greater diminution of temperature which the dampness occasions. Many persons are not so strong, by any means, in damp weather. It is possible that it

<sup>a</sup> Dr. Watson's "Lectures on the Principles and Practice of Physic;" Lecture 7; "Medical Gazette," Volume 27, Pages 226 and 227. (No. 675; November 5, 1840.)

may act by conveying away the electricity in too great a quantity. In dry weather, we are all active and vigorous; but in damp weather, there certainly is a degree of languor,—an inaptitude for action, both of body and of mind, which most persons notice.

*Sleep.*—The effect of cold upon the body, is much increased by sleep. In sleep, the powers of the body are less; the pulse is slower; the heat is not so high; and all noxious agents are less withstood. It is a common remark, that if a person go to sleep in a draught, he is sure to take cold; but if he contrive to keep awake, he will most probably escape.

Cold, too, appears to be more dangerous when applied to the back part of the body, than to the front;—in consequence of the less endowed power there, than in the anterior parts. Persons will escape if a little draught fall upon the face; whereas, if it come to the back of the head or neck, they for the most part experience ill effects.

*Sympathy.*—Inflammation is sometimes excited as a *sympathetic* occurrence. But when I say that inflammation is excited by sympathy,<sup>a</sup> I do not *explain*<sup>b</sup> the fact; I merely *express* the fact. When one eye is inflamed, the other, without any external cause, may also become inflamed; and this is called a sympathetic result;—it is said to occur by sympathy. If a child's head be inflamed, it is common for the abdomen to become likewise inflamed, either the intestines, stomach, or liver; and *vice versâ*. It is of the highest importance, in practice, to look out for this circumstance; or treatment may be addressed to only one inflammation, when two exist.

*Metastasis.*—Metastasis is also another mode in which inflammation occurs. When inflammation of the parotid glands in "mumps" ceases, the brain may become inflamed; or what is more common, the testicles, or one testicle; and this inflammation often affords an illustration of atrophy, as the result of inflammation. It is very common, indeed, for a testicle, when it has been inflamed after mumps, to waste away; so that nothing will be left but the membranes. In gout, metastatic inflammation continually occurs. When the gout suddenly ceases in an extremity, it is very common for inflammation, of an apoplectic nature, to take place in the head; or for inflammation to occur in the stomach or intestines.

*Absorption of Morbid Secretions.*—Occasionally inflammation is induced by the introduction into the blood of unhealthy or acrid matter. If pus, or any other diseased secretion, be absorbed, it is very common to find a deposition of it, at a distance from the part in which it was originally formed. We have a deposition of pus, or of lymph, at a distance;—in the various viscera, in the cellular membrane, or even in the secreting cavities; or we have inflammation and disorganization without deposition. Probably inflammation of the veins takes place; since the pus formed in them does not cause inflammation in distant parts; here it is deposited; but pus, lymph, and other things, are there produced by extravasation only. If distant inflammation take place, there is of course a deposition of pus or lymph; marked by debility, great irritation, and a sallow hue of the countenance.

It has been said, that the *predisposing* causes to disease will sometimes become

<sup>a</sup> From *συμπάσχω*, to suffer with.

<sup>b</sup> The reader is referred to Müller's "Physiology," translated by Baly, and Bichat's "General Anatomy," for an exposition of the physiological laws upon which these sympathetic phenomena are explained.

By the former eminent physiologist they are considered under the separate heads of—

1. Sympathies of the different parts of one tissue with each other.
2. Sympathies of different tissues with each other.
3. Sympathies of individual tissues with entire organs.
4. Sympathies of entire organs with each other.
5. Sympathies of the nerves themselves.

It is most probable, as suggested by Bichat, that the apparent *translation* or *metastasis* of disease from one organ to another remotely situated, is due either to the *reflex influence* of the nervous system, or to the circulation throughout the system of some morbid agent;—inducing the same specific action in a distant organ, the structure of which is similar to that first affected.—*T. Williams.*

*exciting*,—merely by their continuance and increase; so that no “*exciting*” cause, properly so called, is necessary. This may be the case with regard to fulness of blood. A part may become more and more filled with blood,—congestion or determination of blood (whichever it is called) may increase, till at last inflammation occurs; or if it be the head that is affected, a state of apoplexy may be produced, without any actual exciting cause. In *specific* inflammation this cannot be the case; for no predisposition would have the effect of producing small-pox, unless the exciting cause were applied.

*Proximate Causes.*—Such are the observations which I have thought it necessary to make, respecting the *remote* causes of inflammation. The *exciting* causes,—those which are essential to the existence of the disease,—in fact, the actual state of the parts in inflammation, have been already considered in a former section.<sup>a</sup>

## SECTION VIII.—DIAGNOSIS AND PROGNOSIS OF INFLAMMATION.

The *diagnosis* of inflammation, when the inflamed part is visible during life, or when we make an examination after death, has been already spoken of sufficiently;<sup>b</sup> but if it happen that we have to make a diagnosis, during life, respecting a part which we cannot see, then of course it must be founded upon something else than if the inflammation were visible.

*Deep-Seated Inflammation.*—When an invisible part is inflamed, there is almost always pain increased upon *sudden* pressure,—frequently upon the most *gradual* pressure; and there is generally more or less pyrexia and “*symptomatic fever*.” The pain is often throbbing; and frequently there is a sense of weight and tension. It is to be remembered, however, that although a part be inflamed, *gradual* pressure may sometimes be borne; and that, on the other hand, very *slight* pressure,—a mere brush of the surface, may cause pain, when there is *no* inflammation. In neuralgia,<sup>c</sup>—when a person is labouring under *tic douloureux*, for instance,—we may sometimes produce the most agonizing pain, by brushing the surface in the slightest possible manner. But that is not the case where there is inflammation. Such a slight touch does not produce such an intense effect; and (more than that) if a slight touch do produce so great an effect, it is only in inflammation of the skin; and that we can see.

If we are in doubt,—notwithstanding that the pain is increased by pressure, and that there is pyrexia,—the best way, if the patient’s powers will allow it, is always to treat it as an inflammation; and we frequently find, that the blood which is drawn away fully justifies our presumption. The blood is frequently buffed, or cupped, or both; but even if it be not, and there be strong reason to treat the case as inflammation, we must not suppose there is less reason to imagine ourselves right, *simply* because the blood is not buffed. Generally, however, it will be found buffy, if there really be inflammation.

*Prognosis.*—With regard to the *prognosis* of inflammation, we must consider, on the one hand, the age of the patient, and the evident powers of his constitution; and, on the other, the violence of the disease, the degree of disposition to it, and its seat. The danger of the affection depends on the power which the patient has, from the beginning, to sustain the attack. Much must depend upon his age, and upon the general state of his constitution; and much depends, likewise, not only on the intensity of the disease, and its liability to increase, but on its seat. An exceedingly violent inflammation, in an extremity, might not be half so dangerous as one less violent in certain viscera. It is necessary, also, to calculate upon any idiosyncrasy, whether natural or acquired, in the individual. I have already mentioned<sup>d</sup> a patient, who had merely a rheumatic affection of the external part of the head; but he had previously had his skull fractured; and the irritation on the out-

<sup>a</sup> Section III, at Page 82.

<sup>c</sup> From *νῦρον*, a nerve; and *αλγος*, pain.

<sup>b</sup> In Sections I and II, at Pages 73 and 79.

<sup>d</sup> See Page 113.

side of the head, produced sufficient irritation within, for violent delirium to ensue; so that he was in a most violent state of phrensy. There was no danger in this;—it gave way to the ordinary treatment of rheumatism of the external part of the head; but had there not been this idiosyncrasy, it might have been feared that an inflammation of the brain, of a highly dangerous character, was set up. When the man took a glass of spirits, the same effect, I understand, was always produced. We have therefore to consider, whether there is any idiosyncrasy or not; for, whether the disease be inflammation or any other complaint, if the patient be nervous, there may be great depression of the system; and the quickness of pulse, and the general disturbance, may unnecessarily alarm those not aware of the peculiarities of the constitution.

## SECTION IX.—TREATMENT OF INFLAMMATION.

### *a. Active Inflammation.*

*Stimuli.*—In the treatment of *active* inflammation, the first point is to lessen the ordinary stimuli to which the body is subjected, both externally and internally. Excessive action is going on, or there is excessive activity and excitement; and our business is to lessen all the stimuli which maintain that activity. The *external* stimuli may be diminished by exclusion. In the first place, we exclude a high temperature;—so that its stimulus may act as little as possible. In attending to this point, however, great care must be taken not to allow the temperature to fall too low; for if we chill a patient labouring under inflammation, we not only cause great discomfort, but most likely increase the affection. By diminishing the circulation in healthy parts too much, it is possible we may increase the activity of those which are inflamed; so that in lessening the temperature around a patient, it is necessary to diminish it only so far as is comfortable to him.

*Cold Applications.*—With respect to the part itself, the temperature there is too high; and to that part cold may be applied. Cold may be applied by means of plain water; which generally answers as well as any lotion that can be applied, if it be continually renewed; but, of course, we can procure a lower degree of cold, by the use of evaporating fluids,—those which evaporate more quickly than water. It is often of great use to employ real ice; and for this purpose a bladder may be half filled with it, and laid on the head after it has been shaved, or on the front of the chest, or on any other part of the surface that requires it. If we *fill* the bladder, it will not accommodate itself well to the part; but if it be only *half*-filled, it presses down in close apposition with it. If it be the surface itself which is inflamed, and not the interior of the head or chest, it is not well to apply ice in this way; because the pressure would do harm. Indeed, in inflammation of the chest, cold is not applied externally; it is only in cases of hæmorrhage that we have recourse to it. If the surface, then, be inflamed, it is best to apply plain water, or iced water, or evaporating lotions; but, in the case of internal inflammation of the head, or hæmorrhage from the lungs, ice is one of the best things that can be resorted to.\* In hæmoptysis of a decidedly inflammatory character, I have never seen the application of ice attended with harm. Some have said that the application of cold, in the case of inflammation within the abdomen, has been of use; but I am not aware that such is the case. Certain inflammatory pains of the head have given way to a stream of cold water applied to it, when nothing else would succeed. By means of a tube, a stream of water has been applied to the head, for many hours in the course of a day; and the complaint has been thus cured, when evaporating lotions did not answer the purpose.

\* The reason why ice is a more powerful refrigerant than water, is that a great quantity of heat is absorbed (becoming "latent" or "combined") in converting it from a solid to a liquid form. While any of the ice is unmelted, the water remains at the same temperature as the ice itself.—*N. Rogers.*

When the surface is abraded, or when it is a mucous membrane that is inflamed,—such as the interior of the mouth, or the conjunctiva of the eyes (which is very similar to a mucous membrane),—it is generally found of great service to combine, with the cold water, a small portion of the diacetate of lead; but not sufficient to irritate the part. When the surface, however, is not abraded, I doubt whether the employment of lead is more efficacious, than that of plain cold water, or an evaporating lotion.

*Warm Applications.*—The very opposite treatment, however, is often equally beneficial. If we apply warmth and moisture together, we often produce as good an effect as by the application of cold. It is only a speculation; but I imagine that the reason why two such opposite agents produce the same effect, is this:—If we apply cold, we lessen the stimulus;—we lessen the heat of the part;—we lessen the quantity of blood in all the vessels; and, therefore, we lessen the tension; whereas, if we apply warmth and moisture, we cause a relaxation of the inflamed part;—we soften the solids, and in that way the tension is taken off. I presume the cold lessens the stretching cause; whereas the moisture allows the part to be easily stretched,—to give way to the distending fluids. Perhaps the warmth and the moisture applied to the surface, may relax the ends of the vessels, cause a free perspiration, and in that way ease the parts. Such, however, is the fact;—that one patient will be as much relieved by warm applications, as another will by cold. I have myself frequently suffered violent external inflammations; and one part of the day I have found the greatest relief from iced water, or from a stream of cold water constantly applied; and when that ceased to produce ease, or caused pain, then I have experienced the greatest comfort from the application of warm water and flannels. The feelings of the patient are the best guide, in the application of these means. I never apply cold when it is uncomfortable. If once the patient be allowed to become uncomfortable, it may not only produce general chilliness, but make him ill, and perhaps increase the inflammation.

The temperature of the part, however, is not the only thing to be attended to. If we know that the part affected is one greatly influenced by other surrounding stimuli, (as the head, for example,) we should likewise exclude *light* and *noise*; and should, in all such cases, prevent conversation,—both of the patient and of others; so that he may be kept as free from stimuli as possible. The exclusion of light is an important point to be attended to, in all affections of the head, and particularly of the brain.

*Diet.*—Still pursuing the plan of exclusion, we should give the patient but little food; and even that should be of the most inert kind. In fact, we should starve him without letting him know it;—pursue starvation in disguise. Plain water would be the best thing, in many inflammatory complaints; but we must allow toast-and-water, or barley-water;—for the purpose of satisfying the patient. In consequence of the thirst, a great deal of drink must be taken. This should be cold, unless the patient wish to have it warm; and if the drinks be made acid, they are of course so much the pleasanter. A saline draught is a good thing; but a few ounces only will be productive of little benefit. The patient should have a pint, in the course of twenty-four hours, if it be designed to exert a beneficial influence.

*Blood-Letting.*—But although these things are highly important, the great remedy in this disease, is the loss of blood. That is,—we have not only to *exclude* the *external*, but to *remove* the *internal* stimuli; and the great internal stimulus of the body, is the blood. Blood-letting may be performed anywhere. The object is to withdraw blood; and not merely so, but to make as great an impression upon the system, by a given loss of blood, as possible. Hence it is generally good practice to make a large orifice in the vein (if we open a vein); and to make the patient sit up,—so that he may faint quickly. If the blood be drawn with great rapidity, a far greater effect is produced, than if it be drawn slowly. A large orifice tends to accomplish that object; and if a patient be sitting up, he is far more likely to faint, than if he be lying down. When we are sitting up or standing, the blood finds more difficulty in returning to the heart, and escapes more easily from it; and there-

fore, if there be causes tending to produce fainting, they are far more likely to occasion it in that posture, than if we are recumbent. If it be an object to spare blood very much, and yet make as great an impression as possible, it is well to have two veins opened at once,—one in each arm; and to make the patient stand up. The loss of a very few ounces will then produce fainting.

The rule for taking away blood, in general, is not to consider the quantity, but to consider the effect;—to do every thing calculated to occasion a great effect from a given quantity; but, while doing so, to go on till the pulse sinks, till the patient experiences relief, or till an evident improvement takes place. In any of these circumstances, it is well to stop the bleeding, especially if the patient grow faint; lest the depression become too violent. If, however, the faintness cease, and yet the pulse continue the same; or if the patient feel no relief; or if, when he has not fainted, but there has been an improvement of the pulse, the pulse should fall back into its former state; or if, again, there have been no syncope, no improvement of the pulse, but a great improvement in the patient's feelings,—a great diminution of the disease, and yet the pain all returns;—then, in any of these circumstances, we should let the blood flow again. In general, one never orders a particular quantity of blood to be taken away, in an acute disease; but is rather guided by the effects produced.\*

We sometimes find, on bleeding, that the pulse, so far from diminishing, will increase in volume; and so far from becoming slower, will become quicker; and will still retain its firmness. This circumstance may be a very great improvement. There are some diseases in which the pulse is oppressed;—in which the pulse may be large and firm enough, but seems to have scarcely any activity in it. It is not a fluttering pulse; but it moves heavily,—if I may so speak. In what is commonly called “an *oppressed* pulse,” there is plenty of volume,—plenty of firmness; but very little impetus. This is often the case in affections of the head. The pulse is frequently, at the same time, very slow, but is not necessarily so. A pulse may be oppressed, and yet not slow; or there may be a morbid slowness, and yet the pulse may not be oppressed. The one or the other may be the case; and yet, on bleeding, the pulse will rise. It will be sharper, or quicker, or both; and this is as much to be considered an improvement, as diminished force and frequency in other instances; and I would arrest the flow of blood in both cases. I would then wait and see whether things relapsed; and even if they became slower, or heavier, but still having sufficient volume,—it would be advisable to let the blood flow again.

\* Dr. Alison, in his admirable Essay on Inflammation, in the “Library of Medicine,” observes that “the efficacy of blood-letting in lessening the extent and intensity of inflammation, would appear to depend upon two principles;”—to which, indeed, the powers of all other antiphlogistic remedies are referable;—first, “it weakens the heart’s action,” and secondly, “it causes a derivation of blood from the affected parts.” “In both ways it diminishes the quantity of living matter in which the peculiar changes comprised under the term ‘inflammation’ are going on; and whatever be the precise nature of the changes, as it is certain that the blood is an agent essentially concerned in them, it is easy to understand that the greater the quantity of blood sent to the affected parts in a given time, the greater amount of these changes, and particularly the greater quantity of effusion from the vessels (with which we have seen that the danger of inflammatory diseases is most connected) will take place.” He treats the first principle by considering it under two heads;—in the first place, he shows that, under certain sthenic forms of inflammation, “the heart’s action is *weakened* by the absorption of the stimulus by which its motion is habitually excited and maintained,” and this quite in conformity with all that has been established by the labours of Dr. M. Hall on “the effects of the loss of blood;”—a man than whom medical science has known no greater benefactor in modern times. Dr. Alison then proceeds to show “that the difference, observed, of the effect of blood-letting in the erect and horizontal posture, proves that the loss of blood may powerfully affect the heart through the intervention of the central portions of the nervous system.” The second leading division includes the principle of *derivation*;—abstracting a portion of the diseased blood from the inflamed parts, and thus lessening the diseased action. On the important question of blood-letting, as a remedy in inflammatory disease, we earnestly recommend to the reader the perusal of Dr. Marshall Hall’s works on the loss of blood.—*T. Williams.*

The repetition of bleeding, after an interval of some hours, or of a day, must depend upon the same circumstances. When the pulse becomes quicker or fuller again, or the symptoms become worse, then we should follow the same rules in repeating blood-letting, as we originally did. In violent inflammation there is, in general, more difficulty in making a patient faint, than when the inflammation is less violent, or when there is very little the matter with the patient. I believe it is true that very frequently in inflammation, a degree of bleeding will not occasion fainting, which in health, or in a state not far from it, would produce syncope.\* This great principle was established by Dr. Marshall Hall.

But although these are the general rules to be observed, it may be necessary to act in the very opposite manner. If a patient be very plethoric, so that it appears necessary to take a large quantity of blood; if it appear that, without copious depletion, the disease can only be temporarily subdued; and that all the symptoms may return, on account of the great fulness of the system; or if it so happen that the patient is nervous, and thus easily disposed to faint;—in either of these cases, it may be a great point to prevent syncope, before the desired quantity of blood has been withdrawn; and therefore it may be right to bleed from a moderate orifice, instead of a large one; and to make the patient lie down for some time, and then proceed to take away blood. If nervous fainting be expected, instead of syncope from the absolute loss of blood;—if it be likely to rise more from emotion of mind, than from the abstraction of blood, a small orifice should be made; and the patient should also be made to lie down:—in order that the depletion may be carried far enough to make an impression on the system. If fainting occur when one or two ounces only have been taken away, cupping or leeches should be employed. When a patient does faint in ordinary bleeding, the latter should be stopped, and the patient laid down;—lest the fainting become excessive.

*Pulse.*—Though a quick, full, firm, wiry, or jerking pulse, with the symptoms of inflammation, may justify bleeding; yet the absence of any of these states of the pulse, will not forbid bleeding, if the symptoms themselves demand it. If there be no extraordinary debility of the pulse,—no feebleness of the constitution; if there be neither tender years, nor extreme old age;—if none of these circumstances forbid free bleeding, we may have recourse to it, notwithstanding that the pulse gives us no such indication. The pulse may not *indicate* bleeding; but still it may *justify* bleeding. The pulse (as we have already noticed<sup>b</sup>) has been called by Celsus “res fallacissima,”—“the most fallacious of all symptoms;”<sup>c</sup> and, if we depend on the pulse alone, we shall be led into error. The pulse will give us highly important information; but if there be a sufficiency of other symptoms to point out the nature of the case,—to show that the person is labouring under an inflammatory affection, though the pulse would not lead to such a conclusion, we must treat the case in *spite* of the pulse;—provided, however, that the pulse does not indicate such debility, as would evidently make bleeding improper; or that the constitution and age of the patient do not forbid it. In the most dangerous cases of peritonitis,—when the patient was obliged to lie upon his back, with his body and even his thighs raised, so as to relax the peritonæum as much as possible; and where the abdomen could scarcely bear the pressure of the bed-clothes,—I have known the pulse scarcely different in volume, or force, from what it was in a state of health. Notwithstanding that the peritonæum is a serous membrane, I have witnessed the pulse without any great firmness,—any wiriness,—any jerking state;—without any thing that would lead to the supposition that there was disease of this investing membrane. We continually see females, in a state of pregnancy, with a small pulse;—such as would prevent the thought of bleeding, unless there were other modifying symptoms; but from pressing the part affected, we find bleeding indicated; and from attending to the countenance, and looking at the patient, we see that bleeding will be borne. In the cases of peritonitis to which I have

\* From *συν*, *with*; and *κρῆνω*, *to strike down*.

<sup>b</sup> See Page 61.

<sup>c</sup> Book 3, Chapter 6.

just referred, I have seen the blood, after it has been taken away, both buffed and cupped; and the patient has speedily recovered after a loss, perhaps, of forty, fifty, or even sixty ounces. But it is the same with every other symptom. The symptoms should be taken together, and reliance should seldom be placed on any one alone. Every one is important in itself; but every one has also its *relative* value.

*General* bleeding is superior to *local* bleeding. It is speedy, and it is powerful. However local the inflammation,—however remote from the heart (even in inflammation of the testicle, or of the finger in paronychia or whitlow),—venesection<sup>a</sup> is more powerful and far more quickly productive of an impression upon the disease, than any local bleeding.

*Venesection and Arteriotomy.*—In affections of the head, I believe that venesection in the arm is just as good as arteriotomy.<sup>b</sup> The great point, in an acute disease, is simply to get a large quantity of blood from the system in as short a time as possible; and venesection in the arm will generally answer every purpose. At least, I have never seen any thing to make me prefer opening an artery, in a case of inflammation of the head, or inflammation of the eyes.

If a vein cannot be opened, then I would certainly, in any case of dreadfully violent inflammation, open an artery. It is always safe to open the temporal artery. If blood could not be obtained from a vein, in a *very* dangerous complaint, instead of troubling the patient with cupping or leeches, the temporal artery should be opened; I know that some practitioners have opened the radial artery. But opening the temporal artery is safe; and generally affords as much blood as is required.

*Quantity of Blood.*—I have never had occasion to take away more than thirty ounces of blood at a time; except in one instance, in which forty were required to induce syncope; nor do I recollect having had occasion to take away more than eighty ounces altogether, in an acute complaint. Of course, many hundreds of ounces in *chronic* complaints have been taken away;—pursuing small bleedings for many weeks, or months. It is right to mention, however, that some practitioners have taken away an immense quantity of blood, in acute diseases, in a very short time; and with success. In inflammation of the lungs, one hundred and fifty ounces of blood are said to have been abstracted in a few days. In the tenth volume of the “*Medico-Chirurgical Transactions*,”<sup>c</sup> Dr. Blundell states that Mr. Hensley (a gentleman on whom he could rely) declared that, in two cases of inflammation of the lungs in men, he had taken away a gallon and a half of blood in five days; and they both recovered. Precisely such a case is mentioned in the “*Medical Gazette*,” for January 3, 1829.<sup>d</sup> Dr. Badely speaks of having taken away five quarts in five days, in a case of peripneumonia; and with perfect success.<sup>e</sup> If a case be very obstinate, and will not yield to proper treatment, we see what there is authority for doing; for the above are undoubted facts. I do not condemn such practice; but I have never had occasion to have recourse to such profuse evacuations.

*Red Particles Diminished.*—Two Swiss physicians, Drs. Prevost and Dumas (of Geneva), who have made many experiments on the blood, say, that when blood-letting has been employed, the red particles are found, after a certain interval, to be fewer in number. There is not only a change, in the disappearance of the buffiness; but venesection lessens the number of red particles in the blood. We know, indeed, that when blood is taken away from an individual in health, its effect is to impoverish the blood. It is now ascertained, however, in a scientific manner, that the red particles are diminished; so that in blood-letting we not only diminish the mass of the blood, but also lessen its stimulating qualities. We lower its quality, while its quantity is diminished.

<sup>c</sup> Page 307.

<sup>d</sup> No. 57; Volume 3; Page 158.

<sup>e</sup> See the “*London Medical Gazette*,” for March 1, 1828. (No. 13; Volume 1; Page 368.)

*General, and Local Bleeding.*—Besides *general* depletion, however, it is sometimes necessary to have recourse to *local* bleeding. The latter is usually employed on account of the less violence of the general symptoms; the smaller powers of the patient; and the existence of mere congestion of blood, rather than of inflammation. If the general state of the patient's system be not much disturbed; if there be no great excitement or fulness of the pulse; if the patient be very weak; if there be a great accumulation of blood, rather than inflammation; or if the inflammation be rather of a passive or atonic character;—then, in proportion as this state of things prevails, local bleeding is usually preferred to general. But I believe that, in many cases where *local* bleeding is had recourse to, *general* bleeding would be found to answer the same purpose. At any rate, we are never to allow *local* bleeding, which is performed by cupping or leeches, to stand in the way of *general* bleeding. It is frequently a better practice, even if the patient be weak, to bleed *generally* than *locally*;—to set him upright in bed, or to make him stand upright; and from a large orifice to detract four or five ounces of blood, and thus produce a great effect,—than to apply a number of leeches, and drain away perhaps a larger quantity of the vital fluid. I am satisfied that general bleeding is continually omitted, when it might be more advantageously adopted;—when it would produce a much more decided effect, and give far less trouble.

*General followed by Local Depletion.*—I believe that local, is often of great use immediately after general bleeding. We lessen the load of blood in the part, very materially, by immediately applying a large number of leeches, or by cupping. I consider that this is really good practice. General bleeding frequently answers every purpose; but I think I have seen the symptoms disappear still more speedily if, after making a great impression upon the system, and lessening the force of the blood sent to the part, I lessened the quantity contained in the part, by adopting local bleeding.

*Local Bleeding.*—*Local* bleeding may be employed to produce *general* effects. If it be carried very far, a patient may become debilitated by it,—become bloodless. A child, during the operation of leeches, may become exceedingly faint. We may produce these general effects by local bleeding; but it is usually a slow process, and the effects of local bleeding are often very local. In a case of pain of the head, I have seen leeches applied to only one temple; which has been relieved, while the other has not. Frequently, when a patient has had pain of the head, I have seen the occiput cupped, and relief obtained there, while the front of the head has remained as before; and when leeches have been applied to the front, I have known the occiput continue painful. This certainly is not invariably the case; but we perpetually find the effects of local bleeding to be very local. I am not contending against local bleeding. I employ it extensively; but I am always anxious that it should never supersede general bleeding, if the latter be necessary. It is much better to take a decisive line of conduct,—to make a strong impression upon the patient in an acute disease; and then local bleeding, if employed subsequently, has a far greater effect. It is to be remembered that I have been speaking, hitherto, of *active* inflammation.

Local bleeding will sometimes succeed best at a distance from the affected part. I have known chronic inflammatory diseases of the head, that had resisted general bleeding, and local bleeding at or in the neighbourhood of the head, yield to cupping of the hypochondria, or leeches to the anus. Some think highly of bleeding at the foot.

It is certainly a fact, that the detraction of blood from a distant part, is frequently of great utility; and many think of even greater utility than from the immediate seat of the disease. The ancients, or, at least, the older writers, were very fond of it, and supposed that a revulsion was produced;—that the blood immediately rushed from the inflamed part, to that from which the depletion was made. In this country, the circumstance has been too much overlooked. I have had cases of inflammation of the head, (as I shall mention hereafter,) where repeated local bleedings, even till the patient became pale, proved of no avail; but

on taking away blood from the sides of the trunk,—far enough from the head,—the relief was perfect, and the patients recovered. I have had several cases of this description. There can be no doubt that the application of leeches to the anus, will frequently produce the most decided relief, in affections of the head, and indeed even of the heart. Whether it be more efficacious than local bleeding from these parts themselves, I can scarcely say. On the continent, this mode is commonly resorted to; but, from delicacy, it is not usual in this country.

*Bleeding from the Anus.*—When two or three parts are affected at the same time,—as, for instance, the head and stomach,—it is frequently a good practice to take blood from the anus. One can easily imagine why great relief should be obtained from blood being taken away from that part. The veins there go to form the “vena portæ;” and therefore a great load is taken from the liver,—a great load is taken from the whole venous system; and less blood goes to the heart. As the hæmorrhoidal veins run to assist in forming the “vena portæ,” and the later branches through the hepatic veins to the “vena cava inferior,” far greater relief is sometimes obtained by this means, than by any other, in diseases of the heart, and affections situated within the chest, as well as in great congestion within the head. Still, however, it is easy to make assertions in medicine and surgery; and one ought to have a large number of cases registered for comparison,—showing where relief has been obtained, and where not,—before we draw any conclusions. General assertions are frequently not to be depended upon. Extensive and accurate observations are necessary, to enable us to say that one mode of treatment is superior to another. Whether the same quantity taken from other parts would be more or less beneficial, I cannot say; but in affections of the head, I have been frequently surprised on seeing the benefit derived from taking away blood around the abdomen, or from the rectum.

*Position.*—We may frequently diminish the quantity of blood in a part by position; and this is always to be attended to. Position may increase, or diminish the quantity of blood in a part. If a patient have inflammation of the foot, it would be madness to allow it to hang down; or if a patient have inflammation of the hand, it would be equally absurd not to have it kept in a sling. But these things may often be carried farther. In inflammation of the foot, it is often of use, not merely to have it on a level with the body, but to have it raised; and the same is the case with regard to the hand. In inflammation of the head, it would be absurd to allow the patient to lie with his head low. By attending to these points, though we are not doing any thing which will cure the patient, we are doing that which will enable other things to cure him sooner; and we prevent other things from being counteracted.

*Purging.*—To bleeding, in the way of evacuation, purging may be considered next in importance. This, although inferior to bleeding, is highly necessary; for, in the first place, it removes from the interior of the body a quantity of irritating feces, which are almost always diseased, and will most likely become putrid if allowed to remain. We also are sure to find the secretions themselves diseased; in removing, therefore, the remains of food, we also remove such diseased secretion as would be more or less poisonous, or at least irritating. Besides this, we produce an evacuation of liquids from the vessels of the body; and likewise cause a counter-irritation in a part distant from the inflammation. In all inflammatory affections of the head, chest, and various parts of the body, the intestines are disposed to become torpid; the excitement occasioned by the inflammation, causes a depression of excitement in the intestines; and if their excitement be increased, so far as to bring them into full action,—in a proportionate manner we tend to lessen the distant inflammation. It is right, however, not to give any stimulating purgatives; lest we should increase the general excitement. The point is, to give those purgatives which thoroughly empty the intestines of their contents, and subsequently to exhibit such as produce a considerable drain; but, at the same time, we ought to select those which effect the object without great irritation.

*Irritation produced by Purgatives.*—I must here remark, that because very diseased stools are produced, it does not follow that purging is to be continued for

the purpose of bringing the diseased excretions away; for there can be no doubt whatever that purgatives, especially if acrid, will cause a diseased secretion. If a person in perfect health take an acrid purgative, his fæces will not exhibit the healthy character which they presented, previously to the purgative being taken. There can be no doubt that many purgatives, especially if they possess any acrimonious quality, will disorder the secretions, and produce a fetid discharge from the intestines, which would not otherwise take place. It is not necessary that a patient should have diseased secretions, in inflammation and other diseases, before we administer purgatives. It is often not the case; and it is to be remembered that, after a time, when the fæces would otherwise assume their natural appearance, they may be kept in an unnatural state by the administration of purgatives.

*Repeated Evacuations.*—The repetition of purgatives, as well as of bleeding, must be regulated by the violence of the disease on the one hand, and the strength of the patient on the other.

*Diaphoretics.*—With respect to other evacuants, I do not think much of them. Venesection and purging are by far the chief diaphoretics. Sudorifics are not always good; for the skin will resume its healthy function, and the patient perspire without them. If we bleed the patient well, starve him, exclude stimuli, and apply such remedies as I shall presently speak of, we may generally neglect the skin as well as the urine. In inflammatory complaints, when the disease is combated, the urine will come round, without any direct means; and so will the skin. At any rate, stimulating sudorifics do great harm. With regard to antimony,—as it is generally exhibited in inflammatory complaints, for the purpose of producing a moderate diaphoresis,—we may just as well treat the patient without it. A few drops of “vinum antimonii potassio-tartratis,” in a saline draught, cannot do material good in a severe inflammation. So trifling is the power of small doses of this medicine, that I had patients at St. Thomas’s Hospital, who took two or three drachms every three hours to show how it can be borne, without the production of any sensible effect whatever. The idea of a few drops of antimonial wine producing any serious effect, in inflammation, is absurd. If the disease be combated with local and general bleeding and purging, small doses of it are just as well omitted as not; and I never think of saline draughts, or a few drops of antimonial wine, or any other such petty things, for the purpose of curing inflammation.

*Counter-Irritation.*—There is, however, another plan to be followed, in the treatment of this disease;—namely, to exhibit counter-irritants, or (as they are called) “contra-stimulants;” in order to produce a strong impression upon the system. The chief of these are colchicum, digitalis, antimony in very full doses, and mercury. In violent inflammation, and indeed in many violent morbid states of the body, all remedial agents are opposed. In fever, or inflammation, or insanity, or spasm, we may give far larger doses of medicine than could be exhibited in health. In the violent pain of tetanus, for instance, an ounce of laudanum may be given. In inflammation, an ounce of digitalis in twenty-four hours has been given. I never did; nor have I given a scruple, or half a drachm, of the powder, in the same time. As to mercury, we may give a quantity which, in the same individual in a state of health, would induce the most violent ptyalism,\* and cause all the teeth to drop out. In violent inflammation, the effect of bleeding is resisted by the heart. The system is in a new state; and many things will not produce that effect, which they would if it were in its natural condition.

*Digitalis.*—Of the first of the contra-stimulants which I have enumerated, I have had no great experience. I have little or no knowledge of the use of digitalis in inflammatory diseases. I know that some say they can cure inflammatory affections with it, unaided by venesection;—but I have really a horror of digitalis. I have seen so many people die suddenly under its use, that whether they died from it or not, it is a medicine of which I am particularly shy; and—knowing the effect of bleeding, together with some other remedies—I have not had recourse to it, in

\* From πτυαλίζω, to spit.

any quantity sufficient to control the circulation. I have exhibited it in the dose of a scruple, or half a drachm of the tincture, three or four times a-day; no useful effects, however, have resulted in inflammatory affections.

*Colchicum.*—With respect to *colchicum*, there can be no doubt of its extraordinary powers in active rheumatism and gout. So strong an anti-inflammatory remedy as colchicum, must produce sweating, purging, and vomiting; and nausea has a great tendency to lessen inflammation. Nevertheless, I cannot state that I have been so satisfied with it, as to place much confidence in it. With the exception of its employment in gout and rheumatism, its utility has not appeared to me so decisive, as to induce me to exhibit it in preference to mercury.

*Antimony.*—*Antimony* may be given in far larger doses than could be imagined. It is now nearly twenty years since I found antimonial powder<sup>a</sup> to be, in general, a very inert preparation. I have seen others give two or three grains three or four times a day, or five grain doses at night, with the view of promoting perspiration;—ordering the patient, at the same time, to take plenty of gruel, to bathe the feet in hot water, and put plenty of clothes on the bed; and if he has sweated profusely, it has been all attributed to the antimony. Seeing these things, I was in doubt as to its powers; and I went on until the dose exceeded a drachm, and even amounted to two drachms, three times a-day. This satisfied me that its want of effect could not arise from the remedy being resisted; and I therefore gave it to patients labouring under itch. It is well, when a patient is rubbing in sulphur, to give something internally, to gratify his wish to have his “blood purified.” In the cases to which I am referring, I gave the antimony with no effect. I once prescribed *one hundred and thirty* grains three times a-day, without its even producing nausea. The patient took it to see how far we might go. There was little the matter with the man; and as I found that he took one drachm, and then a drachm and a half, of antimonial powder, three times a-day, with no more effect than would have resulted from “powder of post,” I gradually increased the dose, till he took the quantity I have mentioned. This fact shows the uncertainty of the remedy. It contains a great deal of phosphate of lime, and peroxide of antimony; and sometimes it contains nothing else; but if given with calomel, it may sometimes produce nausea. I will not say that antimonial powder, as it ought to be, is an inert remedy; but as it is commonly procured, it may be given in the quantity I have just stated, in a large number of cases, without any effect.

In reference to “*antimonii potassio-tartras*,” it may be given in large quantities. Many patients in St. Thomas’s Hospital took half-ounce doses of antimonial wine, in chronic bronchitis, every four hours, without experiencing nausea. They said, when first taking it, that it made them sick; but such a state did not continue. Many persons give twenty grains of tartar-emetic, in the course of twenty-four hours; and in inflammatory complaints, I have given two grains every two hours. This at first induces nausea or vomiting, which soon ceases, though, after going on for perhaps a fortnight, the patients may be sick again. It has not produced the salutary effect I expected. *Colchicum* and *digitalis*, like tartar-emetic, cannot be depended upon like mercury. I have given colchicum and antimony repeated trials; and I am not contented without great success in inflammation; because I think it ought, generally, to be cured. It is an established truth, however, respecting tartarized antimony, that in inflammatory diseases it may be given in large quantities; and that, although a patient may be made sick at first, the sickness will go off, and the remedy be borne. I have generally, however, seen the sickness come on at the end of about a fortnight; and then persist as long as the remedy was continued.

In administering antimony, the object is to depress the system, by inducing nausea. The dose required, however, in different cases, to bring about this result, will vary with individual peculiarities of constitution. In some there is a great *tolerance* of its effects. This is exemplified, although not strikingly, in a case

<sup>a</sup> “*Fulvis Antimonii Compositus.*”

which occurred at St. Thomas's Hospital, a bronchial inflammation with a tendency to tuberculous deposit. The employment of mercury being contra-indicated by the latter circumstance, antimony was given; and the patient took it for several days, at the rate of a grain every four hours, without the occurrence of nausea. The frequency of the dose was afterwards lessened. This in addition shows that antimony, like digitalis, may produce *cumulative* effects.

*Mercury.*—I have instituted comparative experiments with antimony and mercury; and I am quite certain that the success of those who employ antimony, in addition to bleeding, is very inferior to the success of those who employ mercury. In violent inflammation, I really make it a matter of conscience to employ mercury. If there be great danger, as in violent inflammation of the larynx,—where the patient, if neglected, would die in a few hours,—I do not hesitate to give ten grains of calomel, every two hours. In this case, if we do not bring our means to operate very speedily, the patient will be suffocated in a moment;—he will fall back in bed (from œdema in the glottis), and the case will be over. In other instances, however, there is no occasion to be so active. Five grains every four hours will do very well; or, perhaps, rather less. In a case where life appeared to be in danger every moment, I have given as much as a scruple, every two hours. These, however, are extreme cases; in which we are very sure that, if we do not instantly save the patient's life, he will slip through our fingers. If the mercury begin to run off by the bowels, it is better to unite it with opium. It very soon does this; and we see the necessity of resorting to opium; or, if there be an objection to this remedy, we might give an infusion of catechu, which is one of the most powerful astringents. Astringents in *tinctures* must be injurious in inflammation; and it is therefore better to give an *infusion*. Kino, as far as I know, is as good as catechu. If the calomel run off in spite of all we can do, “*pilula hydrargyri*” may be exhibited; but “*hydrargyrum cum cretâ*” is still less likely to do so; and with this a person may be salivated very readily. It is stated, in some books, that salivation cannot be produced by it; but I have salivated many with it. A dose of ten grains may be given every two or three hours; but I think it has a greater tendency to produce sickness, than any other of the three forms of mercury we have mentioned. More patients become sick while taking “*hydrargyrum cum cretâ*,” than while taking either calomel or blue pill. It is frequently necessary to unite it with opium.

*Salivation.*—It may be right, also, to rub in mercury externally,—on the extremities and abdomen,—as quickly as it can be done; for the best plan is, to get the mouth sore as quickly as possible. It is right, at every visit, to examine the gums; and likewise to press the glands under the lower jaw, and smell the breath. The moment any symptoms of an affection of the mouth appear, the remedy should be suspended;—it certainly should not be continued. In some cases, the affection of the mouth will exceed the point desired; but it is better now and then to have a violent pytalism, and save nearly all our patients, than to be fastidiously particular.

When the mouth becomes too much affected, the chloride of lime, or of soda, are the best applications. If one ounce of the solution be mixed with six or eight of water, and the patient's mouth washed with this lotion every hour, you will find that the pytalism will readily subside. If ulceration have taken place, time is required to heal it. If we employ the chloride before ulceration has occurred, no subsequent soreness, from the inflammation of the mouth, takes place. It should be employed of a strength just sufficient to be felt by the patient. It is also to be remembered, that if we maintain a free state of the bowels, there is much less danger of a violent affection of the mouth; and if the mouth become affected, and we open the bowels freely, we generally diminish the affection to a certain extent.<sup>a</sup>

<sup>a</sup> In the Meath Hospital, Dublin, great relief was found to ensue (in cases of excessive pytalism) from the application of leeches below the angle of the lower jaw.

I can state, as a positive fact, that if bleeding be properly had recourse to, and we produce a certain degree of affection of the mouth, it is very rare indeed for a patient with acute inflammation to be lost;—unless there be some organic disease which keeps up the irritation; or unless our efforts be counteracted by something wrong in diet, or by some violent emotion of the mind, which must be more than a match for all the best remedies.

The use of mercury, I beg particularly to state, is not to make us employ less bleeding beforehand, or at the time of exhibiting it. So far as there is occasion for bleeding, it should be put in practice whether mercury or any other remedy be employed; but it will be found that, as the mercury produces its effect upon the mouth, the necessity for bleeding will diminish. Bleeding is the great remedy,—the “sheet anchor;” we therefore should bleed according to the necessity of the case, without considering whether mercury is being administered, or not. But the addition of mercury causes the bleeding, which is put in practice, to be tenfold more efficacious, and so lessen the necessity for its repetition; but it can never become a substitute for bleeding. Dr. Armstrong used to say, that bleeding was the right arm, and mercury the left arm of medicine, in the treatment of inflammation;—a pithy declaration of an important fact.

I would strongly advise the perusal of Dr. Duncan’s “Medical Commentaries,” published in 1788. All we know now, relative to the use of mercury, was known then; though it has been considered, that the facts known with respect to the use of mercury, in many local inflammations, were first generalized by Dr. Armstrong. The general fact is fully stated by Dr. Hamilton. It is singular how often many of us, who know excellent practical things, do not bring them into use when we come into practice. It is a sort of inertness which is apt to come over us. The paper to which I refer, is by Dr. Hamilton, of Lynn-Regis. He says that he learned the use of mercury from a navy surgeon;—that having been informed by a navy-surgeon of the great use of mercury in inflammation, he gave it in pleuritis, in hepatitis, and other inflammations; which yielded in the most extraordinary manner under its use,—in a way that he never found before by any practice he adopted.

*Opium.*—There are some cases, in which it would be very wrong to employ opium;—for instance, in phrenitis. But in cases where it is not specially contra-indicated, it is a practice with some to give a full dose of opium, after a copious venesection; and, as far as I know, it is a very good practice. Two or three grains of opium, after venesection to syncope, will frequently prevent the necessity of another bleeding; or, at any rate, will send the patient into a quiet sleep, by which he will be very much refreshed. Unless there be inflammation of the head, this practice is not objectionable. If the bleeding be likely to cause great irritation, or if the patient be weak, it may be a highly proper practice. It may be wrong to omit it; because it may prevent that morbid irritability,—that restlessness which sometimes takes place after bleeding; but it ought not to take the place of mercury. The chief point should be, to endeavour to arrest the inflammation by free bleeding, which, if it be thought advisable, may be followed up by the local detraction of blood; and a dose of opium may then be given. We should also be as anxious to give mercury, as though that were itself the chief remedy. Mere bleeding will cure many cases; and so will mere starvation; but if we give mercury, the exceptions to a cure will be reduced to a very small number indeed. With respect to opium, it is better to give one full dose, than repeated small doses; for it is found that opium has a stimulating effect over the body. Hence the pulse becomes fuller, and there is thirst. Under small and repeated doses of opium, both thirst and heat will continue. Dr. Wilson Philip made experiments illustrative of this subject. He applied, to a denuded brain, a small quantity of opium, and likewise of tobacco; and, on looking at the distant capillary vessels in the extremities, he found them very much excited; but if he applied a large portion of either of these ingredients, he found the action diminished;—just the opposite effect. This demonstration of the effect of large and of small doses, is perfectly in harmony with what we all observe, when we give large and small doses of these remedies. A small quantity

of tobacco, for example, will excite feverishness;—will make a person hot and thirsty during the whole of the night; whereas a considerable quantity will depress the pulse, produce a cold, chilly sweat, and lower all the powers of life. So with respect to opium; if its sedative effects be wanted, it should be given in one full dose. This would be dangerous, if we did not bleed; but it is perfectly safe if we have depleted the patient copiously in the first instance.

*Excessive Depletion.*—Supposing, however, (as is very likely to happen,) that the patient has been bled too much, even then we find opium of the greatest use. If too much blood has been lost, and the patient has headache, throbbing of the temples, frequent syncope, deadly faintness, great rapidity of pulse, vertigo,—and this is a state frequently seen in women who have lost a great deal of blood during or after labour,—then the chief remedy is opium. All these symptoms are much diminished by it. Stimulants, of which ammonia is one of the best, and good nourishment, are highly proper; but the extreme restlessness of the body is very much alleviated by the addition of opium. In such a case as this, if we cannot prevail upon the patient to eat, it is necessary to use the stomach-pump; and strong broth should be injected, both into the stomach and the rectum.

*Local Depletion.*—But notwithstanding this state of the system, a local congestion of blood occasionally takes place;—so as to render it necessary to apply leeches. When the body has lost so much blood, that we are obliged to give ammonia, and nourishment, and opium, we sometimes find such a tightness of the head,—such a degree of heaviness from local congestion, that the application of leeches, or of ice, is indispensably required. These matters, however, cannot be learned minutely by precept. The requisite knowledge can only be acquired by personal observation. Cases present themselves in which the abstraction of four ounces more blood, would certainly precipitate the patient into the grave.

*Local Counter-Irritants.*—Mercury, colchicum, and the other remedies mentioned, are *general* counter-irritants; but in the treatment of inflammation, we have also frequently to put in practice *local* counter-irritation;—that is to say, to set up a new action in the neighbourhood, or at a distance. I stated<sup>a</sup> that purgatives chiefly act in this way;—not only in removing a quantity of stimulating fæces, but by exciting the action of the intestines, and so far diminishing action elsewhere. But we also employ certain downright stimulants to the surface; and of these, blisters and sinapisms<sup>b</sup> are perhaps the chief.

*Blisters.*—It is best, I believe, to apply a blister on the surface over the internal part inflamed;—as over the right hypochondrium, in inflammation of the liver; and over the thorax, in inflammation of the lungs; but with respect to the head, this is a dangerous practice when there is any active inflammation going on. The application of cold to the head is beneficial in inflammation of the brain itself, or of its membranes; but early stimulating the vertex, by a blister, is highly injurious. Nothing can be worse practice, than to apply blisters to the top of the head in phrenitis, in the early stages of the disease; when, however, the patient has been sufficiently evacuated, then such a measure is very proper. But with respect to other parts of the body, it is best to apply blisters immediately over the internal part which is inflamed.

*Sinapisms.*—If it be desired to produce an effect rapidly, a mustard-poultice is one of the best applications. Some persons excite blisters, by causing the steam of boiling water to play upon the part; and others by putting boiling water in a jug, with a napkin in it, and suddenly inverting it; but I think a strong mustard-poultice, beat up with hot vinegar,<sup>c</sup> will produce an effect as speedily as, in general, is to be desired. In young children, ordinary blisters are often very dangerous; and a mustard-poultice,—applied to the abdomen, or the back of the head, or the chest,—will produce as great an irritation as is desirable; and one which can be

<sup>a</sup> See Page 124.

<sup>b</sup> From “sinapis,” *mustard*.

<sup>c</sup> Some experiments at the Hotel Dieu have tended to show, that the mixture of vinegar rather diminishes, than adds to, the stimulating properties of the mustard.

controlled, by removing the sinapism, when the child expresses great distress. A mustard-poultice, applied for ten minutes or an hour, over the chest or abdomen, oftentimes proves useful.

*Solution of Cantharides.*—Some persons have introduced a solution of cantharides, as a substitute for blister-plaster. I made some extensive trials with it at St. Thomas's; because it appeared a desirable thing to be able to produce a blister, by merely varnishing a part with a brush. It is a much cleaner application than that of an offensively-smelling plaster, which a patient has to keep in bed with him for twenty-four hours; but it does not well answer the purpose. A blister was produced, but not immediately;—frequently not till the next day; and then, when it was going to heal, a fresh blister would arise. In many instances, a far more violent blister was induced than I desired; and sometimes it did not succeed in causing any vesication. Upon the whole, it appeared very unsatisfactory; I considered it, therefore, preferable to continue the old practice, of applying a common plaster of cantharides.

### *b. Atonic and Passive Inflammation.*

*Atonic Inflammation.*—In that form of inflammation in which there is little power,—in inflammation which is called “atonic” (where there is not only inflammation, but likewise a state of debility),—we must employ less evacuants, and trust more to mercury and opium. Where patients are debilitated altogether, I should certainly place great reliance upon mercury (combined with opium), for the purpose of lessening the morbid irritability of the system; and should make the evacuant means chiefly local. I should employ local bleeding; or perhaps should frequently trust much more to blisters, or the application of cold, than even to local bleeding. Still, as I mentioned before,\* it sometimes may be a better practice, even when there is debility, to produce a momentary effect upon the system, by causing fainting;—by taking away a few ounces of blood suddenly, in an upright posture. But, as a general rule, when patients are of very weak constitution, one would trust more to local than to general detraction of blood. In these cases, while we take away blood locally, or while we are producing syncope by the detraction of a few ounces, it may often be necessary to give good nourishment. When there is violent inflammation in a part, and little power in the system at large, it is not at all inconsistent to lessen the inflammation of the part by local evacuants, and by cold; and yet to support the whole powers of the system by beef-tea, milk, and other nourishing articles of diet. The latter, but not stimulants, are admissible.

*Passive Inflammation.*—The same remarks apply to what is called “passive inflammation;”—that is, when a part is not actively inflamed, but rather in a state of congestion; and the affection is not so much in the constitution, as in the part itself. In inflammation of the throat, where the throat is very much swollen, and of a dingy colour, without active symptoms; and frequently in inflammation of the eyes, in which there is more congestion than real active inflammation, local means are by far the best. It is not desirable to produce an impression on the system; but to unload the part,—to remove the congestion of blood; and therefore local means are exceedingly proper. In such cases, even stimulating applications to the parts are useful. They are in a state of atony; and by stimulating applications, and by astringents, we may frequently remove the unhealthy condition, even better than by mere local evacuations.

It is of the highest importance to make a correct diagnosis between an active inflammation, and one of an atonic kind, and a state which is hardly, perhaps, to be called “inflammation.” After an inflammation has been very active, the symptoms will continue; but they are very much modified;—being attended with great debility, and great morbid irritability. Here the remedies of inflammation

\* See Page 123.

will make bad worse. It is necessary to remember that, in almost every case of inflammation, this stage may arrive; and it is also necessary to remember, that this set of symptoms may happen in the first instance;—bearing so great a resemblance to inflammation, that one not practised in it might fall into error. This particularly occurs in inflammation of the brain. Children sometimes display many of the *symptoms* of arachnitis, or acute inflammation of the membranes of the brain (“hydrocephalus acutus”), but without that disease;—we see patients labouring under sudden and violent delirium, without the presence of inflammation; or at least so little, that debility, inducing morbid irritability, is the prominent feature of the attack; and if, in these cases, blood were taken away, life would most likely be destroyed. The mode of distinguishing these cases, is by observing that there is no great pain; or that, if there be any pain, it is slight and transient; and that, in the next place, the pulse, although it may be quick, is feeble;—it is not a pulse which, upon careful examination, would appear to justify us in resorting to depletory measures. Then, again, the surface is frequently by no means hot; or, if it be hot, it is only so in a transient manner; and the expression of the face altogether is one of weakness. I shall have to speak upon this subject at greater length, when, in the consideration of particular diseases, I come to treat of hydrocephalus and delirium tremens; but in every case of inflammation it is possible, that after we have treated it actively, and subdued its active nature, the patient may fall into a state of morbid irritability; and local symptoms, though not of an active kind, may still exist. We can judge of it only by finding that, whatever local symptoms there may be, still the pain is not sharp; that if not gone entirely, it is much reduced; and that the pulse is one which will not justify bleeding. There is a degree of feverishness, so that the pulse may be very rapid; but still it is a pulse of irritability;—one that may be almost extinguished by the finger; and an expression of feverishness is observable.

*Administration of Stimulants.*—In these cases, we must no longer go on with evacuant means. They are highly dangerous. It is necessary to administer good nourishment, and even stimulants; and sometimes to give opium. Such a case may occur, not only after excessive bleeding, but after inflammation has subsided spontaneously. It is particularly seen in children, in spurious hydrocephalus\* (if I may so call it); and likewise in delirium tremens (a spurious sort of phrenitis);—not invariably, however; but in many instances. In such cases we have sometimes even to give wine, and also brandy; but the utmost care is required, and we continually meet with cases, in which we cannot satisfy our mind how far active inflammation may still exist; or how far it is a mere case of irritation;—where we may sit anxiously pondering over every circumstance, and be unable after all to determine what course to pursue. In these instances, I should advise a combination of both plans;—that is to say, support the strength, give moderate stimuli with the greatest caution, and anxiously watch their effects; and, at the same time, cautiously employ evacuants locally. After the use of any remedy, we should carefully observe the effects; and draw our conclusion from its action. For example: if leeches were applied while giving nourishment, it may be soon seen, by the effects, which is the more proper; and that must be afterwards steadily pursued.

### c. Chronic Inflammation.

With regard to *chronic* inflammation, its treatment must depend entirely upon the circumstance of its being active or passive. We have little to do with the

\* This state of the system frequently involved the physician in confusion and *malaprazis*, previously to the discovery of its true nature, by Dr. M. Hall and Dr. Gooch. Dr. Hall, by whom these affections of children were first described, called them “hydrocephaloid diseases.” He has graphically shown them to depend upon an exhausted and anæmiated condition of the body,—the very opposite of that which accompanies inflammation; and requiring, therefore, remedies of an opposite character;—support and nourishment, rather than depletion.—*T. Williams.*

duration of the complaint. We are not to consider whether it is *acute* or *chronic*; but whether it is *active* or *passive*; and what are the powers of the patient. We frequently have occasion, for example, to bleed in rheumatism which has existed for a year or two. I have met with cases where, after rheumatism has existed two or three years, the parts have been so hot that it would have been vain to attempt to cure them without local bleeding. It is true that, when the disease has continued so long, the powers of the patient will seldom be very great; but we are not to consider what is *likely* to be the case, but to ascertain what the patient's powers *really* are;—what is the degree of activity of the disease; and what proportion it bears to the strength of the patient. In these chronic cases, we should make use of chronic remedies. We can apply, not only leeches and cupping-glasses from time to time, but also means which are not serviceable in active inflammation;—that is to say, issues, setons, and caustics,—so as to produce external ulceration. In *acute* inflammation, whatever is done must be done rapidly; but in the *chronic* form, we can apply setons or moxæ;—we can burn the part, or apply caustic and repeated blisters, or keep blisters open; and we can also produce great irritation by the application of tartar-emetic. Any of these applications may be serviceable in the highest degree.

*Nitrate of Silver.*—There is one form of caustic which is frequently of great use, even in certain acute inflammations, which is nitrate of silver. In certain inflammations of the skin, the application, wetted and rubbed on the part, or a strong solution applied with a brush, is frequently of great use. There is sufficient testimony in its favour; but I have not employed it extensively myself. In one form of violent inflammation of the skin, however, I have made a circle all round the inflamed part. I have not touched the inflammation itself, but a certain portion all around,—so as to blacken it; and I have seen it put a limit to inflammation, which threatened to spread to a great extent. Inflammation is thus arrested which, in all probability, would have run on to destruction of life.

*Organic Diseases.*—I have remarked<sup>a</sup> that, in *acute* inflammation, when depletion (both general and local) has been carried as far as is admissible,—the pulse being still quick and compressible, with considerable irritation,—there is reason to suppose that the case is now one of irritation; and we therefore have to support the patient well;—perhaps to give stimulants, and quiet him by opium. So, too, in the treatment of *chronic* inflammation; when we have persevered for a great length of time; and when, notwithstanding all we have done,—constant evacuations,—constant draining,—constant abstinence, we find that the signs of local inflammation still continue, we have reason to suppose there is something more than mere inflammation;—that it is not simply chronic inflammation we are treating; but that there is organic disease, which keeps up this chronic inflammation. In disease of the liver, it is impossible, for the most part, to say whether there is mere chronic inflammation, or organic disease of various descriptions, as tubercles, unless we can feel tubercles forming upon its surface, or can feel a considerable enlargement of the organ. It is only when we find, notwithstanding all the rational means employed, that no progress is made against the disease, we begin to suppose that there is something more to be dealt with than inflammation.

In this case it is wrong to go on with mercury, or with antiphlogistic measures, to any extent. Such measures only increase the mischief. The patient must be well supported. For the most part, he will gradually sink under his complaint; but we must take care not make him sink sooner than he otherwise would. In tubercular, and most other organic diseases, by supporting the patient well, tranquillizing him with opium, and attending to the general state of the constitution, we may protract life, and mitigate suffering; although we cannot cure the disease. If we take it up too hastily, inflammation that might otherwise be subdued, will not be overcome; but if it be taken up too late, and the disease be treated as inflammation that may be subdued, dissolution will certainly be hastened, and the patient will sink so much the sooner.

<sup>a</sup> See Page 131.

*d. Terminations of Inflammation.*

In the treatment of what are called "the terminations of inflammation," it is well to remember what I stated formerly;<sup>a</sup>—that it does not necessarily happen that the inflammation ceases, because the (so called) "terminations" take place. They are circumstances which take place; but the inflammation does not cease because these circumstances occur. When any of these circumstances take place,—as effusion, suppuration, or mortification,—we must always inquire whether inflammation is still present or not, and if it be present, to what extent; and likewise of what character,—whether active and tonic, or attended by debility; for the same remedies may be necessary, as were requisite in the treatment of mere inflammation, before these "terminations" took place. We have to treat the inflammation present accordingly as it is *active*, or more or less *passive*; as it is tonic,—attended with strength of constitution; or according to the power of the constitution, whatever may be the activity of the part itself.

*Effusion and Suppuration.*—We have also to treat effusion and suppuration as *inflammatory* or *not inflammatory*; because there is sometimes no inflammation. If it so happen that fluid is generated,—whether that circumstance has taken place which is called "effusion;" and which is merely an excessive secretion or collection in a serous membrane; or whether suppuration has taken place, so that matter has collected,—in either case, it may be necessary to let out the fluids; because fresh symptoms may arise from their pressure. This is frequently necessary in a collection of pus; and also in the case of mere effusion, or of fluid collection, in a serous membrane. We may liberate the lungs, and avert impending danger, by allowing the escape of fluid effused in great quantity into the thorax; and some say we may do the same with respect to the pericardium; but of that I never knew an instance. It may sometimes be necessary in the case of the peritonæum. With respect to pus, however, the escape of it by art is of the utmost importance; because it not only injures by its mechanical pressure and distension, but frequently causes great mischief to the constitution, by its peculiar properties. If the matter be confined, the system is sometimes in a state of great depression (the tongue brown, and the pulse feeble); but on making a free incision, and letting out this fluid, the constitution will rally,—perhaps in the course of a day. When there is a mere collection of serous fluid, (whether diseased or not), diuretics are frequently very useful; but for the most part, the remedies of inflammation, moderately continued, are among the best means. By still giving mercury, and by continuing low diet, we cause absorption of the fluid to take place; and, what is much better, we prevent its increase; and if we can but effect that object, nature, in a large majority of cases, will herself accomplish the evacuation. Among the remedies that answer both purposes, colchicum and digitalis will be found useful. They will perhaps lessen the action that is going on, keep down the fluid, and also tend to lessen previous effusion. Colchicum—owing to its exciting the kidneys and alimentary canal—is particularly suitable; and so is mercury.

*Nourishment without Stimulation.*—If a discharge has been accomplished by art, or if nature herself have effected a new opening, then we find it necessary to support the constitution well, for the purpose of enabling her to bear this copious discharge; but still it is frequently necessary to adopt more or less of an antiphlogistic regimen;—to give abundant nourishment; though not, indeed, of a stimulating kind.

*Ulceration.*—We may see good reason for not supposing that the necessity of antiphlogistic treatment is over, even in the instance of ulceration and of mortification; which are also called "terminations of inflammation." An ulcer is frequently due to nothing more than the surrounding inflammation. In the case of a sore nipple, I have oftentimes seen this. When the breasts have been so sore, that the mother dreaded the agony of suckling her child, the ulceration has frequently been

<sup>a</sup> See Page 93.

cured, by merely applying leeches at some little distance from the spot, but still on the breast;—subduing the inflammation there, and afterwards keeping it down. So in the legs;—it is very common for an ulcer to take place in them, and yet not to heal; simply because there is so much inflammation around. Here plasters and ointment are of no use; but if we bleed the patient well, and purge him, we take off the tension and fulness of all the vessels. We subdue the inflammation, and then nature has power of her own to heal the ulcer. It may be just the same with respect to all the terminations of inflammation.

*Mortification.*—Even in mortification, we have to consider whether or not inflammation is going on; and whether it is attended by tolerable strength of constitution, or not. Inflammation may attend mortification after it has begun, and when it is decidedly going on. The inflammation may be really active;—there may be great redness of the part, great pain, and great heat; and there may be tolerable strength of the constitution at large. On the other hand, the inflammation may be more of a passive kind;—the part may be dingy, swollen, and not in much pain; and the constitution may be in a deplorable condition as to strength. It is often necessary, particularly in mortification, to employ local antiphlogistic means, while supporting and sustaining the system at large. The system itself is in a bad state; and therefore we have to give the best of nourishment, and perhaps wine, or even brandy; whereas the part itself is disposed to run into a state of excitement; and mischief arises from such treatment, unless we prevent the action of the part itself;—perhaps by the application of leeches, or of cold. Occasionally, in mortification, it is wrong to employ soothing measures. We must adopt means of the most stimulating description; but it is to be remembered that, frequently, the more we stimulate the part, the greater will be the mortification. If there be great irritation, a poultice of carrots or turnips answers a very good purpose. The more we irritate, in many cases, the greater will be the extent of the mortification. If, however, a stimulus be absolutely necessary, I consider the oil of turpentine the best. Sulphuretted oil is often very good. When the constitution was well supported, I have seen the mortification stop, apparently through these applications; but these things are to be employed only when there is no violence of local inflammation.

*Factor.*—It is always an object to prevent the gangrenous parts from injuring those which are not yet in a mortified condition. There can be no doubt that putrid animal substance is, in the highest degree, poisonous; and it is very necessary to prevent it from acting on the living part, and also to prevent the stench which proceeds from it. The latter may be removed, pretty easily, by charcoal-powder put into a fermenting poultice. Stale beer-grounds and yeast are very serviceable; but, above all, I should recommend the chloride of lime, or of soda, to be continually applied. In using these applications, however, it is necessary to remember, that they must be continually applied;—not two or three times a day; but as one portion of the solution of the chloride dries, so a fresh portion must be employed,—to counteract the putrescent tendency. For the most part, they are inefficiently employed; and, unless you look after nurses and attendants, they will not apply them sufficiently to remove the stench.

*Bark, Ammonia, and Musk.*—In mortification, bark was formerly much praised; and was even thought to be a specific. But that cannot be the case; for there is sometimes great excitement of constitution,—requiring antiphlogistic means. At other times, however, in an opposite state of the system,—where there is mortification with debility,—bark may be of great use, and especially sulphate of quinine; for, in mortification, it is common for the stomach to reject bark. I have frequently seen mortification apparently arrested by a combination of musk and ammonia. I say “*apparently*,” because, in such a case, it is our duty to support the constitution. Musk and ammonia united, and given every few hours, have been particularly extolled by some practitioners. In nearly all these cases of mortification, opium is useful. There is great general suffering,—great general

restlessness; and it is an object to lessen the suffering, and tranquillize the system at large.

*Amputation.*—It might be supposed, that the removal of the gangrenous part would put a stop to the mortification. On reflection, however, it will appear to be bad practice. The mortification of a part depends, generally, upon the state of the constitution; and the fresh wound caused by amputating the mortified part, will fall into the same condition; because it is not the *part* that is so much in fault, as the *constitution*. If, however, the mortification depends entirely upon local circumstances, the mortified part may be cut off with safety. Supposing an artery has been injured to such an extent as to cause its obstruction, and that the part supplied by it dies from the want of blood, the part may be removed without any danger whatever of the disease spreading; because the mortification depends upon a local cause, and not upon the constitution; and the fresh wound will not fall into the same predicament as the mortified part. In almost every case, however, where the mortification does not depend upon a local cause, it is the best practice to wait till nature herself has pointed out that the mortification will not spread;—till a line of separation has begun; and till we see that the powers of the constitution are sufficient to repair the injury;—that the constitution is not in a condition for the mortification to spread higher up; but that, on the contrary, nature is capable of the healing process. Then we remove the part, and effect the object that nature herself was carrying on. It is of great importance, in the treatment of mortification, to recollect these few particulars.

### *e. Specific Inflammation.*

The observations that I have now made refer to *common* inflammation; but I stated that inflammation may also be *specific*;—and that we term inflammation “specific,” when it runs a very peculiar course, or arises from a peculiar cause.<sup>a</sup> Gout is termed “a specific inflammation;” because it runs a very extraordinary, and very peculiar course. Small-pox is also an instance of specific inflammation. It not only runs a peculiar course;—beginning on a certain day, and undergoing certain changes on others; but it arises from a special cause, which will produce no other disease. Gonorrhœa, also, is a specific inflammation;—having its origin in a cause that will induce no other disease.

*Prophylactic Treatment.*—We sometimes adopt prophylactic measures, and can prevent these affections altogether. Small-pox may be prevented, in the majority of instances, by the cow-pock.

*Specific Remedies.*—For some of these diseases we have a specific remedy. For itch, which is a specific disease, sulphur is the remedy; for syphilis, mercury. For the greater part of these specific inflammations, however, we have no specific remedy; and even if we had, it would still be of the highest use to treat them on the principles of common inflammation. Even where certain remedies are at command;—as in the case of itch or syphilis,—we must, notwithstanding, keep in view the remedies of common inflammation; because it must be recollected that *specific* is *common* inflammation, with something superadded to it; and by adopting common treatment, in addition to specific, the cure is much accelerated.

*Mixed Inflammations.*—Some inflammations are specific at one time, and not at another. There can be no doubt, that, in general, ophthalmia is not a contagious disease; but we have every reason to believe that sometimes it is. Even erysipelas has appeared to be contagious. I think I have seen a person die from erysipelas caught in this way. Some strong reasons (which I shall notice more particularly hereafter) for supposing it to be contagious, will be found in a paper published by Dr. Wells, late of St. Thomas’s Hospital. Catarrh is sometimes specific. A common “cold” is an instance of common inflammation; but now and then there is an epidemic catarrh, which depends upon some peculiar cause in the

<sup>a</sup> See Page 111.

atmosphere, and not on the common causes of inflammation. It is a singular fact, that inflammation may be specific at one part of its course, and not at another. Gonorrhœa is an instance of specific inflammation at first; but no doubt, after a time, it ceases to be contagious. When that time arrives, we do not know; and therefore it would be bad policy to speculate on the presumption of its having occurred; but I think it is pretty certain that inflammation in the urethra, sufficient to keep up a discharge, will continue long after any contagion is to be feared.

## CHAPTER II.

### HÆMORRHAGE.

NOT only do the essential symptoms of inflammation (such as swelling and pain) sometimes arise from other causes; but even other circumstances that usually occur in the course of inflammation, and what are called its "terminations," are sometimes present without it. Among the circumstances which take place in the course of inflammation or its terminations, are discharges and collections. These may sometimes be mere results of inflammation, or closely connected with it, and sometimes they may occur without any inflammation at all. One of these discharges consists of blood; another is a discharge of mucus; another is not a discharge, but a collection of serous fluid. A discharge of blood is called *hæmorrhage*; a discharge of mucus is called a *flux*, or a *catarrh*, or a *gleet*, or a *profluvium*; and an excessive collection of serous fluid, that cannot be discharged, is called a *dropsy*.

[The term "*hæmorrhage*"<sup>a</sup> signifies the bursting forth of blood from the living body;—the escape of the blood from those vessels in which it is always contained in a healthy state of the system.

In the present day a very large class of important diseases is collected together, and described under this title,—"*Hæmorrhage*." Whether the extravasated blood escapes from the body by some of the natural external openings, or remains pent up in some closed cavity or viscus;—whatever may be the cause of the extravasation of the blood, still the morbid phenomenon would, in the present state of medical science, be classed among the hæmorrhages. It frequently happens that a very considerable loss of blood is sustained, in consequence of some accidental injury of the arteries or veins, or by ulceration of their coats. Whenever the vessels so injured, or the trunks from which they arise, are within the scope of the senses of sight and touch, the surgeon is called upon to arrest the hæmorrhage by the application of the ligature. It is not our intention to consider any of those forms of hæmorrhage which more properly belong to the province of surgery; we simply state, that all those hæmorrhages which are consigned to the care of the surgeon, are the result of appreciable injury of the blood-vessels. Those forms of hæmorrhage which are usually committed to the care of the physician, are much less perfectly understood; they frequently take place without any perceptible alteration in the anatomical condition of the part whence the blood escapes; and are therefore controllable with less facility and certainty. They arise from some pathological condition of the body itself, and may be entitled *spontaneous*.<sup>b</sup>]

*Tissues from which Hæmorrhage occurs.*—There is scarcely a structure of the body which may not suffer from the spontaneous effusion of blood from its vessels. Hæmorrhage frequently occurs in inflammation of a mucous membrane—particularly of the mucous membrane of the intestines and of the urethra, and less fre-

<sup>a</sup> From *αἷμα*, blood; and *ῥύμι*, to break forth.

<sup>b</sup> "Library of Medicine," Volume 5; Page 1.

quently in inflammation of the bronchia; but it is a common occurrence to see the most violent inflammation of a mucous membrane, without the escape of a single drop of blood. Why it happens that inflammation of a mucous membrane should, in one case, be attended by hæmorrhage, and in another not, I do not think we can explain; but such is the fact. A discharge of blood, whether profuse or not, will frequently take place without any violent inflammation. We see that inflammation exists; but we cannot believe it is the sole cause of the hæmorrhage. That the hæmorrhage is accompanied by inflammation, is all that we feel justified in saying; nor can it be stated that it is the result of an inflammation.

Although it is generally the mucous membranes which pour forth blood, the skin, without any abrasion, has been known to do the same. I never saw an instance of the kind, but I have read of bloody sweats; and they occur in persons who have been bitten by some poisonous animals. Curious cases are to be met with in authors, of blood oozing from various parts of the body. In an American journal there is an account of a person from whose cheek blood suddenly oozed in considerable quantity, without any abrasion.

*Vicarious Discharges.*—Ulcers will frequently afford a great quantity of blood; but this especially occurs in women whose menstruation is deficient. There have been some curious instances of the vicarious discharge of bloody fluid. If menstruation be suppressed, it is not uncommon for an ulcer to break out on the legs, and to bleed once a month; or, if there have been an ulcer before, it may take on a bleeding character. I have seen hæmorrhage from the chest take place in the same way. Hæmorrhage has taken place once a month; simply because the menses were suppressed.

On some occasions, though rarely, hæmorrhage occurs from the serous coverings of the lungs, heart, brain, and abdominal viscera. It likewise occurs in the cellular tissue of many parts of the body; as in the parenchyma of the brain, lungs, liver, and testicle.

*Mode of Escape of the Blood.*—[It will be interesting, and productive of a better understanding of the pathology of hæmorrhages, if we first consider the conditions under which the blood escapes from the vessels of the different tissues. It is true that hæmorrhage from some of the before-mentioned organs,—as the stomach, the intestines, the lungs, and the brain,—does occasionally result from the rupture of some vessel or vessels of cognizable magnitude; but it is no less certain that, in by far the greater number of these spontaneous hæmorrhages, there is no lesion of structure, either of arteries or veins, so far as the most careful dissection informs us. To “break or burst a blood-vessel,” in the most literal meaning of those words, is thought by the public, and by some at least of the profession, to be a misfortune of very common occurrence; yet, relatively to the frequency of hæmorrhage, it is certainly a very rare one. (*“Cyclopædia of Practical Medicine.”*) The opportunity here afforded of dissipating a widely entertained error, ought not to be neglected; and we shall therefore not hesitate to reproduce the principal arguments by which the doctrine of hæmorrhage by exhalation is supported. As hæmorrhages from mucous membranes are far more frequent than from other tissues, so will they afford us the readiest means of establishing this principle in pathology. Thus, where hæmorrhage has occurred so profusely from the stomach or bowels, that the death which ensued has been sufficiently accounted for by the mere loss of blood, the whole tract of the alimentary canal has been diligently examined, and has exhibited no breach of surface, nor any perceptible alteration of texture. Sometimes the mucous membrane appears, here and there, of a red colour, and (as it were) surcharged with blood; sometimes it is pale and transparent, while the vascular network, visible immediately beneath it, is gorged and turgid; sometimes the whole is colourless,—the same network of vessels having been completely emptied by the previous hæmorrhage; and sometimes, again, (and this is illustrative of the mode by which the blood has issued,) vast numbers of small dark-coloured masses, like grains of fine sand, can be made to start from the surface of the membrane by slight pressure. There can be no doubt that these are minute portions of blood,

which had remained and coagulated in the vessels or apertures forming the ultimate channels of the hæmorrhage. (Watson; Andral's "Precis de Pathologie;" Volume 2; Page 151.) Numerous and conclusive observations, of a similar kind, might be cited from the records of morbid anatomy, which is so extensively cultivated in the present day, and in this way direct proof is obtained, not only that hæmorrhage may take place from the surfaces of internal mucous membranes by exhalation, but that this is the mode in which it most commonly happens;—that the effusion of blood by any of the natural outlets of the body, can seldom be explained by the detection of any rupture of the coats of a blood-vessel. Bichat also supported this doctrine of hæmorrhage by exhalation by the following considerations; which, although full of physiological interest, are by no means so convincing as the former. He states, that if the uterus of a female who dies during menstruation be carefully examined, we cannot discover either any actual erosion of vessels, or any of those scars which ought to be so numerous, if at each menstrual period the uterus were really the seat of so many successive lacerations of its internal membrane. It may be observed, however, that the process of menstruation cannot be looked upon as a morbid process; as in the unpregnant female, during a certain portion of her life, it is not only consistent with perfect health, but actually essential to it; and as the fluid so poured out is not strictly blood, the analogical argument drawn from the preceding facts in favour of hæmorrhage by exhalation, though it may afford a strong presumption, is not decisive. But any deficiency in the cogency of the two preceding arguments, is supplied by the careful observation of those rare but well-authenticated cases of cutaneous hæmorrhage, where a dew of blood appears upon some part of the surface of the body; and which, being wiped away, again appears, without any perceptible change in the bleeding surface beyond a blush of redness. But it is not only from the observation of mucous membranes and the skin pouring forth blood from their surfaces, that we are assured that hæmorrhage takes place by the process of exhalation. Bichat states, that he had upon many occasions scrupulously examined the internal surface of the peritoneum, of the pleura, and of the pericardium, in cases of hæmorrhage from those membranes; and that their surface appeared to him entirely free from any laceration; so that it was very evident to him, that the exhalants had poured forth the blood, in place of the serum which they previously secreted.\*]

When hæmorrhage occurs from a mucous membrane, I believe it is, for the most part, from a large number of minute vessels. The profuse hæmorrhage which may take place in a very short time,—so as to prove fatal in a minute or two,—without any vessel whatever being found injured, is surprising. I distinctly recollect having a patient with some pulmonary disease, who was sitting up in bed. Suddenly blood came from his mouth; he fell back, and was dead. On opening him, we found the stomach filled with blood;—there was an immense coagulum, exactly forming a mould of the stomach; but, after examining every part of that organ, with the most minute attention, I could not discover the orifice of any vessel whatever. The same has been observed in the case of the pericardium. I think it is mentioned in Dr. Baillie's work on "Morbid Anatomy," that cases have occurred, both in mucous and serous membranes, in which he was unable to find a vessel which appeared to have poured forth blood. The pericardium, for example, will suddenly allow the escape of an enormous quantity of blood.

[“If it be demonstrated,” says Chomel, “that there does not exist any rupture of the blood-vessels in these cases of hæmorrhage from the mucous and serous membranes and the skin, there remains open to us, in the present state of medical science, only one mode of explaining the escape of the blood;—it can only take place through the same channels as pour forth the mucus, the serum, and the sweat.” (*Dictionnaire de Médecine*.) There seems no more necessity, under the action of disease, for a rupture of vessels to give exit to the blood, than to give exit to these fluids. What the vessels or outlets to which we give the name of “exha-

\* “Library of Medicine;” Volume 5; Pages 2 and 3.

lants" are, how they are distributed and arranged, in what manner they are connected with the ordinary capillary circulation of red blood, or under what influences they are placed, are points concerning which we have little or no certain knowledge. We know, indeed, that such channels must exist, though we cannot see or demonstrate them; and that whilst the health is good, they do not allow the blood, as such, to pass through them. Having thus produced facts and arguments which, as we believe, establish the truth of the doctrine of hæmorrhage by exhalation, it would seem that this class of diseases should be regarded as analogous to morbid secretions, and in any nosological arrangement be placed in the same class with dropsies and mucous discharges; and it is in this light that they have been regarded by Andral.

Another mode in which the occurrence of hæmorrhage has been explained (Andral; "Precis de Pathologie;" Volume 1), and which is principally applicable to the passive forms of the disease, is by a supposed alteration in the consistence or composition of the blood itself; which becomes attenuated, and capable of passing through channels or orifices that healthy blood cannot permeate. In defence of this supposition may be adduced the facts, that hæmorrhages are known to occur where the blood is obviously more thin, pale, and serous than natural; and, still more remarkably, where that fluid has undergone further demonstrable changes in its chemical nature, or is even visibly altered in its sensible qualities; as, for example, in purpura hæmorrhagica, scorbutus, typhoid fevers, malignant small-pox, and erysipelas. These hypothetical attempts to explain the processes by which hæmorrhage may take place, deserve (as Dr. Watson has observed) more attention than has sometimes been paid to them. The views which they involve can scarcely be regarded as mere speculative refinements; for they often exercise a real, though perhaps an unacknowledged, influence upon our practice. At any rate, if they do not, prior to experience, justify certain modes of treatment, they accord wonderfully with what experience has taught concerning the means by which hæmorrhage may sometimes be stayed or prevented. In some cases we succeed by measures which tend to abate the general force of the heart and arteries, and to lessen general plethora; or by diverting partial plethora and restoring the disturbed balance of the circulation, or by directly emptying the turgid capillary vessels. In other cases, we rely chiefly upon expedients which we believe to have the effect of constricting the extreme vessels:—styptics to the bleeding part; cold to the surface of the body, —producing a sympathetic shrinking in other related membranes; or internal medicines, which use has shown to have the property of restraining the natural exhalations when in excess. And, finally, there are cases where we seek, and not in vain, to repair the blood;—to restore it to its natural condition by improvements in diet, or by food of a peculiar kind, such as the juice of lemons; and thus the tendency to hæmorrhage is cured. (*Cyclopædia of Practical Medicine.*\*)]

*Active Hæmorrhage.*—If hæmorrhage occur with signs of inflammation,—with pyrexia,—with a full, hard, or quick pulse; together with pain and heat,—it may then be termed "*active hæmorrhage*;"—just as inflammation is called *active*, in similar circumstances. The disease is then to be treated simply as inflammation; and the hæmorrhage will subside. We have, in general, to bleed the patient; and the blood will generally be found buffed and cupped. As in inflammation, purging will be required; and it is often quite safe and proper to give mercury, keep the patient on low diet, and apply cold. The latter is particularly useful in such a case.

*Passive Hæmorrhage.*—But, like inflammation, hæmorrhage may be *passive*. There may be no pain, or but little; no heat; no pyrexia; no quickness and fullness of pulse; or, if there be quickness, the pulse is at the same time feeble. There may be congestion in a part, or there may not;—that is to say, all the veins may be distended; or the extremities of the vessels only may be pouring forth blood, without any congestion. When hæmorrhage takes place without any symptoms

\* "Library of Medicine;" Volume 5; Pages 4 and 8.

of inflammation,—without pain, without heat, without fulness or quickness of pulse,—the part itself may be in a state of congestion; but the latter condition is sometimes absent. We may, on opening a patient, find great congestion of all the vessels; while, in other cases, we find extreme paleness. Where there is a considerable discharge of blood, without signs of inflammation, but with symptoms of great fulness of blood in the part, I believe in general it is venous. Hæmorrhage of this kind will sometimes be altogether mechanical. There may be an obstruction in some of the leading veins; and the blood may be poured forth mechanically. An obstruction in the spleen, or in the liver, is a common cause of a discharge of blood from the intestines; but this discharge will sometimes take place without any obstruction; in which case there is a peculiar state of the circulating fluids. In typhus fever, in exanthematous fevers, in scurvy, and in that peculiar disease called “*purpura*,” there are peculiar vitiated conditions of the fluids,—inducing corresponding changes in the tissues of the body: which enable us, in a great measure, to account for the constant tendency to hæmorrhage. In bleeding from a wound, the discharge is merely passive,—from the want of mechanical resistance. The want of mechanical resistance, however, will not explain all cases of passive hæmorrhage; because we have cases of the most extreme debility of body, where the patient has no hæmorrhage; and frequently there is hæmorrhage of a passive kind, without inflammation, where there is not such an intense degree of debility.

*Inflammation and Relaxation.*—In these two forms of hæmorrhage, the state of the system is totally different. In *active* hæmorrhage,—that which resembles active *inflammation*,—the blood is, as it were, *forced* out; whereas, in *passive* hæmorrhage, the blood is *let* out. In active inflammation, there is an intense circulation going on in the part; that is, the blood is moving more energetically than natural,—and the *quantity* of blood *moving* through the part is increased; the action of the heart is strong, and the blood is forced out of the extreme vessels. We have, therefore, only to moderate the force of the blood; and the hæmorrhage, for the most part, ceases. But in passive inflammation, the force with which the blood is impelled to the part is not increased. There is no great impulse behind; the blood is altered in quality; and the extremities of the vessels are so relaxed, that it escapes. It becomes, therefore, necessary to employ different means;—not to stop the force of the blood, but to improve it, and restore tone to the extremities of the vessels as much as possible, and to diminish their diameter; so that the blood may not be thus *let out*. In active inflammation, all the astringents, stimulants, and compression which can be employed would do little or no good; for there is an active hæmorrhagic tendency. The blood is driven on with great force; and if we merely treat it as inflammation, the hæmorrhage generally ceases; whereas, in *passive* inflammation, if we were to annihilate the force of the blood from behind, by debilitating measures, we should only increase the relaxation of the vessels, and make them more liable to give way than before.

*Mixed Cases.*—It must always be remembered, that a great number of cases are inflammatory; and that others depend entirely upon relaxation, combined with certain conditions of the blood. In these mixed cases we are under the necessity of resorting to both plans;—of keeping down activity in the part, while we moderately support the system at large. We have to adopt just the same treatment that I mentioned, as necessary in a doubtful, combined case of active and passive, or tonic and atonic inflammation.<sup>a</sup> According as the pulse is not quick,—or as it is not full and strong, or as there is little pain or heat, we may adopt the remedies for passive or atonic inflammation. In proportion as the pulse is strong or quick, and the amount of heat in the part is great, so we must adopt more vigorous antiphlogistic measures. Local means must sometimes be had recourse to, for diminishing excitement; while, at the same time, we support the constitution. But if the hæmorrhage be decidedly of a passive character,—so that to treat it as inflam-

<sup>a</sup> See Page 133.

matory by bleeding and purging is out of the question,—we must trust more to the application of cold to the part itself; and to local, and perhaps even general, astringents.

*Application of Ice.*—Cold may be applied to the exterior of the chest, in spitting of blood, with the most perfect safety. I have known phthisical patients to sit up in a chair, with scarcely any thing upon them, and to have ice laid on their chest; without the least suffering being produced, or any unpleasant circumstances resulting. In hæmorrhage from the kidneys, also, it is a good practice to apply ice to the loins; and in cases of profuse discharge from the alimentary canal, I should not hesitate to give ice by the mouth and rectum, and to place it on the abdomen.

*Astringents.*—I very much doubt the efficacy of nearly all internal astringents, except in the case of hæmorrhage from the alimentary canal; in which case catechu or kino may be employed with great advantage; for then we apply the remedies as locally to the part itself, as if they were applied to the surface of the body, in cases where the latter is diseased. But with respect to those astringents, which are intended to be absorbed, and thus to operate on a distant part of the body, I very much doubt their effect;—unless they are of a saline character, or are readily absorbed. The efficacy of acetate of lead is unquestionable. I have oftentimes proved it to my own satisfaction. But with regard to vegetable astringents, I very much doubt whether, in a case of profuse hæmoptysis, for instance, we can do good, even if we fill the stomach and intestines with catechu and kino.

*Acetate of Lead.*—We may operate, however, on distant parts by means of *metallic* astringents,—provided we give those that may be quickly absorbed; and the acetate of lead is certainly the chief of these. With regard to the dose, it would not be imagined beforehand (knowing the ill effects of lead), that we could give the large quantity that really may be borne. Not only may one or two grains be given every six hours, but two or three grains may be exhibited every two or three hours, for some days, with the most perfect impunity. I know we may give a scruple of it in the twenty-four hours, and even more,—nearly half a drachm, with perfect safety;—provided we carefully attend to the state of the patient's bowels; and I know that such doses are sometimes necessary, because I have found no effect produced till the dose has been brought up to that point. For some time, there is no occasion to push on the doses so quickly; but if the hæmorrhage be obstinate, it is then necessary to do so. I have seen a stop put to the hæmorrhage, when the dose had arrived at a certain point; and when the dose was lessened, the hæmorrhage returned. The only inconvenience I have known to occur, has been violent pain of the limbs. It is especially necessary, however, to attend to the patient's bowels;—to take care that they are freely opened every day; for otherwise it would be madness to give it. With this precaution, however, I consider it perfectly right, in passive hæmorrhage, to give acetate of lead very freely. The pain of the limbs is of no consequence, if life be saved. A patient, on such terms, may well bear pain for some little time after his recovery; but even that pain may generally be removed by employing the warm bath, once or twice a-day, and by the administration of colicum.

*Sulphuric Acid.*—Sulphuric acid is another astringent, which exerts an influence over a profuse discharge;—not hæmorrhage, but profuse sweating. The same effect may result from nitric acid; but sulphuric acid will undoubtedly check the most profuse perspiration.

*Oil of Turpentine.*—The application of cold, of astringents combined with cold, and the administration of astringents internally, are among our chief measures in passive hæmorrhage; but the oil of turpentine frequently answers a most excellent purpose. We have all seen it stop profuse hæmorrhage from the nostrils, by being introduced with a plug of lint; and I have seen a similar effect produced, in hæmorrhage from mortified parts. I do not know that it will stop hæmorrhage from internal parts, except the alimentary canal and the kidneys;—but it will stop hæmatemesis and melæna;—that is, a discharge of blood from the stomach. I have had cases, almost innumerable, illustrating the great utility of this remedy. Oil of turpentine,

which has proved a most efficacious medicine, should not be exhibited in large doses;—as by producing vomiting and purging it might prove injurious; which, in such cases, might be fatal to the patient. Twenty drops should be given, every three or four hours. I have known people take it of their own accord, where I should have been afraid to give it. I have known it taken in active hæmorrhage from the kidneys, and put a stop to it; but where the hæmorrhage was active, I would first treat it as inflammatory; and then, after a time, give oil of turpentine. If the hæmorrhage proceed from a part which can be reached, and we cannot succeed in stopping it by other measures, compression (by means of a ligature, compress, &c.) may be necessary; or even the application of the actual cautery.

*Predisposing Causes.*—With respect to predisposing causes, it is in young persons that we have active hæmorrhage; and it is in middle age and advanced life, that the passive form generally occurs. Of course, there may be exceptions to this general rule. In children, it usually takes place from the nose; in young adults, from the lungs and air-passages; in elderly people, chiefly from the abdomen; but they are likewise subject to hæmorrhage within the head,—producing apoplexy.

Women—old, young, and middle aged—are very subject to hæmorrhage from the stomach; and also, though in a much less degree, to hæmorrhage from the intestines. This hæmorrhage from the alimentary canal in females, is generally of a passive kind; and will generally bear astringents from the first. It does not require any great extent of bleeding. In the menstruating period of a woman's life, however, the uterus is very subject to hæmorrhage; which is often inflammatory. Many cases of menorrhagia<sup>a</sup>—without pregnancy,—without delivery—have yielded to one or more bleedings, combined with low diet; whereas all the astringents that could be given, would be of no use in this *inflammatory* hæmorrhage,—attended with pain of the loins, heat of body, and quickness of pulse.

*Hæmorrhagic Diathesis.*—Besides this predisposition to hæmorrhage from certain parts, depending upon age, there are others depending upon other circumstances. There is sometimes a constitutional tendency. Certain persons are known to be subject to hæmorrhage from certain parts; and some persons are subject to hæmorrhage in general; so that if they have a tooth extracted, they will always bleed profusely; or if they cut their finger, it will continue to bleed for many hours, in spite of the remedies used. There is certainly, in many people, an hereditary predisposition to hæmorrhage. In some of these, an extreme thinness of the arteries has been found. After a tooth has been extracted, it has been found necessary, from the profuse hæmorrhage,—notwithstanding that the actual cautery was employed,—to tie the carotid artery; and it has been found that the arteries were even thinner than the veins in other people.

[The hæmorrhagic diathesis, is a remarkable state of the blood and sanguiferous system, and by no means uncommon in this country; but it seems to be a more common affection in the West of Germany, where all the boys of a family will frequently die with it. It is hereditary; and has been observed to affect males more frequently than females, although it may be transmitted by the mother. The blood is of the ordinary colour, but *unusually fluid*; and, although it is coagulable, the coagulum has little firmness. The consequence of this state of the blood is, that most of the tissues, including the *capillary parietes*, are extremely attenuated and relaxed; and, accordingly, this lax state of the vessels allows the blood readily to transude, upon the application of the slightest force. In many instances, where this latter circumstance happens, no efforts of nature, or means of art, are capable of restraining it. Mr. Wardrop has collected several cases of this description; and mentions several examples, in which this diathesis was evidently *hereditary*.

In the aggravated form in which this disease is described as occurring in Germany, the symptoms are—the appearance of ecchymoses (spontaneously, or from the slightest pressure), which slowly disappear, leaving a yellow tint behind;—epis<sup>†</sup>

<sup>a</sup> From *μηνια*, the menses; and *εγγρημι*, to break out.

taxis;—profuse loss of blood from the slightest puncture;—hæmoptysis from a slight cough;—diarrhœa with clots of blood in the stools. The patients, moreover, are subject to frequent attacks of pain and swelling, with ecchymosis of the wrist, ankle, and knee-joint, attended by fever. On the examination of the bodies of those patients, the vessels were found extremely thin and softened.

Mr. Wardrop remarks, that those substances which dispose the blood to coagulate, seem to have more effect in restraining the bleeding, than those which excite the artery itself to contract. A lad who exhibited this hæmorrhagic tendency, was reduced to the most extreme state of anæmia,—threatening immediate dissolution,—from a trifling surgical operation. Mr. Lane, by whom the case is given,<sup>a</sup> performed the operation of *transfusion*;—the boy was soon reanimated, and ultimately recovered.

Vitiated states of the blood—predisposing to, or causing hæmorrhage—are frequently acquired: these are generally passive and symptomatic hæmorrhages; and for the most part they are *not*, properly speaking, hæmorrhages at all;—being merely exudations of serum, holding the colouring matter of blood in suspension, or solution; and the result of various morbid conditions of the blood. This is exemplified in the petechiæ, ecchymoses, and sanguineous effusions occurring in malignant diseases. Andral remarks, “that it is sufficient for hæmorrhages to occur, that its molecules lose their natural *force of cohesion*.”<sup>b</sup> With respect to many of these cases, and the curious subject of the *sudor sanguinis*, it is to be regretted, that no microscopic observations of the fluids have been made;—the first question which suggests itself to the mind, being—“Are the red particles of the blood effused as such, or do they previously undergo solution?” From the rapid advances which are now being made in organic chemistry, there are some grounds for the hope that these states, depending upon the vitiation of the fluids, will soon be more definitively understood.—*T. Williams.*]

*Exciting Causes.*—The *exciting* causes of hæmorrhage, are whatever propels the blood violently, either generally or locally; and whatever mechanically accumulates it; such as posture, the application of a ligature, or obstruction in any part. Another exciting cause of hæmorrhage, is the suppression of a discharge, or the sudden cessation of a natural discharge; such as the entire or occasional suppression of the menses, the suppression of hæmorrhoidal discharge, or the suppression of diarrhœa. Indeed, the sudden cessation of any disease to which a patient has been very subject, is sometimes attended with hæmorrhage from an internal part. A solution of continuity is a common cause of hæmorrhage; and, of course, it is then of a passive kind.

*Arterial and Venous Hæmorrhage.*—In hæmorrhage which proceeds from the nose or the lungs, the blood is generally florid; while that which comes from the stomach and intestines, is generally of a venous character. But the circumstance of the blood being black, does not necessarily prove that it comes from a vein. It may assume that colour from remaining some time in the stomach or intestines, before it escapes; for blood, if allowed to be perfectly still, and not exposed to the air, will become black. If we tie an artery in two places, the blood between the ligatures becomes venous in its character; and therefore blood discharged from the stomach and intestines, though it may be *venous* in its *characters*, may yet be *arterial* in its *origin*. In apoplexy, the blood effused within the head appears to be venous; but its black colour may arise merely from the reason I have just stated.

The uterus is particularly subject to hæmorrhage during pregnancy, and parturition; but the reason of this is, for the most part, mechanical. Inflammation, if not the cause of menorrhagia in women who are not pregnant, and have not lately been delivered, is, at any rate, a very common attendant circumstance. Menorrhagia that has nothing to do with impregnation, is generally of an inflammatory character.

<sup>a</sup> “Lancet,” 1840-41, Volume 1; Page 825.

<sup>b</sup> “Lancet,” 1839-40, Volume 2; Page 843.

An inflammatory state very often produces hæmorrhage from the intestines and urethra.

In the head, and from the lungs, the stomach, and the intestines, hæmorrhage often arises from merely mechanical causes;—from ulceration, or solution of continuity. One cause of hæmorrhage in the head (apoplexy), is brittleness of the vessels, or tenuity of them, or ulceration of the blood-vessels of the head. Hæmorrhage from the lungs often arises from a mere inflammatory state of the bronchia, or of the air-cells,—constituting pneumonia. In phthisis, nature endeavours to prevent hæmorrhage by forming adhesions, and plugging and contracting arteries; but sometimes an ulcer will produce hæmorrhage, and even sudden death. With regard to the stomach, hæmorrhage will sometimes occur from ulceration; and death may be the consequence. The same thing will take place in the intestines. There may be an ulceration of even a malignant character; and, every now and then, profuse hæmorrhage is the consequence. It will also come on, in many of these parts, from mechanical violence. It is very common for a person to spit blood after a blow on the chest, or a fall. It is also common to void bloody urine after a blow upon the loins; and to discharge blood from the intestines after a fall.

Not only may there be profuse hæmorrhage from the mucous membrane of the bronchia, from the stomach, from the intestines,—from the interior of the kidneys, and from the urinary bladder; but other parts are sometimes the seat of fatal hæmorrhage. I have known hæmorrhage take place into the pericardium, and prove almost instantly fatal; and cases of sudden and fatal hæmorrhage into the spinal sheath, without any evident cause, are recorded. In fatal cases of hæmorrhage into the pericardium, the heart and the pericardium have been found soft. It was so in the case which I saw; and, as far as I can ascertain, it was so in other instances.

## CHAPTER III.

### PROFLUVIA.

FLUXES, catarrhs, or profluvia,\* form the next class of affections which we shall notice. They are precisely similar, in principle, to hæmorrhage; and occur from those parts which are most frequently the source of the latter;—namely, the mucous membranes. Fluxes occur particularly from the nose, the bronchia, the intestines, the bladder, the urethra, and the vagina. Those parts which, during inflammation, frequently pour forth blood, will also, during the same period, pour forth a much increased secretion. In the first instance, their secretion is increased; it afterwards declines, but does not come down to the standard of health; and then, as the inflammation subsides, the secretion becomes excessively abundant. Inflammatory or catarrhal fluxes may therefore occur from the mucous membranes;—like the inflammatory hæmorrhages; and, after all the signs of inflammation have subsided, these discharges frequently continue. There is, however, another form, in which no inflammation is to be discovered;—the mucous membrane pouring forth a considerable quantity of liquid, for some time; and that without the occurrence of any signs of inflammation. There are *passive* fluxes;—exactly as there are passive hæmorrhages. The only difference is, that in the one case *blood* is poured out, and in the other a *secretion*.

*Inflammatory and Uninflammatory Discharges.*—I mentioned, that the skin—which has some relationship to mucous membrane (since it is developed from the latter)—will occasionally, though in very rare cases, pour forth blood.<sup>b</sup> The skin, however, will every day pour forth an immense quantity of its own secretion. The

\* From “profluo,” to run down.

<sup>b</sup> See Page 137.

term "*flux*," "*catarrh*," or "*profluvium*," would not be given to a discharge from the skin; but, just as the mucous membranes pour forth their discharges in excess, so frequently does the skin. Profuse sweating is analogous to profuse discharges from mucous membranes. We have sufficient proof that excessive discharge from the skin is, more frequently than not, quite devoid of an inflammatory character. In fact, in the highest debility, that of syncope,—or of death, the skin will secrete most abundantly. Just so it is, undoubtedly, with respect to the mucous membranes. They will secrete most abundantly, without any signs of inflammation at all. It has been imagined, that whenever the mucous membrane secretes in excess, it must be in a state of inflammation; but I think the instance of the skin, which is alluded to by Andral, is sufficient to show that the mucous membranes likewise may be in a similar state, without any inflammation. He remarks, that the skin will secrete in the greatest abundance,—will sweat profusely, without any marks of inflammation. This instance of the skin would enable us to say, *à priori*, that the same thing is possible with respect to the mucous membranes. But I think, *à posteriori*, we can assert that mucous membranes will secrete most abundantly, without inflammation; for after fluxes these membranes are often quite pale after death;—just as they often are after passive hæmorrhage. It appears to me to be a case analogous to that of inflammation itself; and also to that of hæmorrhage. I think there may be an *active* secretion from the mucous membrane, and from the skin, as in acute rheumatism; or that it may be entirely *passive*,—without any mark of inflammation.

*Treatment.*—The treatment of these fluxes is precisely the same as the treatment of inflammation or of hæmorrhage. If they be of an active kind,—attended with strength of pulse, pyrexia, heat of body, pain of the mucous membrane itself,—the pain that is characteristic of inflammation of a mucous membrane, and is increased by pressure,—astringents are altogether improper. At any rate, they are altogether useless;—just as they are in active hæmorrhage. It would be as absurd to attempt to cure these discharges by astringents,—to stop the discharge of gonorrhœa, for example, during the violence of the inflammation, by an astringent injection,—as it would be to attempt to stop by such means an active hæmorrhage. We have only to lessen the inflammatory state by bleeding, and the discharge will become diminished, or be put into a course of diminution. Perhaps there will be a momentary increase; but it is followed by a diminution, similar to that which occurs in an active hæmorrhagic process. When there is no inflammation present, or the inflammation is subsiding, we may apply local means, as stimulants and astringents, with the greatest advantage. If it so happen that no inflammation occurs from the very beginning, we may at once apply stimulants and astringents. The instance of the urethra is a good illustration of all that occurs in the various mucous membranes of the body. I have remarked<sup>a</sup> that, in inflammation, an increased secretion may happen, both of which are only to be subdued by anti-inflammatory measures; but that at last there may be only a passive discharge; and then anti-inflammatory measures will increase the mischief: stimulants are therefore to be resorted to. Sometimes there will be so little inflammation, that it may be disregarded from the very first. It is quite the same in diarrhœa. In diarrhœa, frequently, the best remedy is to bleed the patient, to starve him, to leech the abdomen, and to blister him; to give no astringents whatever, but sometimes even moderately to purge,—in order to increase the effect of the treatment: the inflammatory state will then subside. In other cases, we have to give astringents and opiates, and support the patient well; and in that way he recovers. It is the same, too, in bronchitis. In active bronchitis, any remedies which stimulate the air-passages, would be highly injurious. It is only necessary to bleed the patient well, to enjoin abstinence, and to treat him as labouring under inflammation; and the discharge of mucus gradually subsides. In an old man, however, a profuse discharge may take place from the bronchia;—forming what is called "*catarrhus senilis*;" without inflammation, but accompanied with emaciation

<sup>a</sup> See Page 144.

and paleness. Tonics and good nourishment form essential steps in the treatment. Such stimulants as snakeroot (*Polygala Senega*) answer the purpose best.

## CHAPTER IV.

### DROPSY.

*Definition.*—THE next class of affections that we have to consider, belong entirely to serous membranes, and the interstices of the serous cellular tissue. In these cases, fluid is secreted in such excess, that the ordinary powers of absorption are inadequate for its removal; and as the serous cavities of the body are shut sacs, the fluid does not escape, as it does from mucous membranes; so that, instead of a discharge or flux, *dropsy* is the result.

[But the term "*dropsy*" has likewise been applied to collections of serous or other liquids in cysts; which are themselves preternatural;—having been formed, or greatly enlarged and altered, by some morbid process. Those effusions which occur in serous cavities, as the direct result of inflammation, ought not to be denominated "*dropsy*." Nor is every collection of serous fluid found in the shut cavities of the *dead body*, and independent of inflammation, to be considered a dropsy. For this is oftentimes only a physical, post-mortem phenomenon,—arising from the accumulation of blood in the venous system; the tissue of which, becoming lax from commencing decomposition, allows the serous portion of the blood to transude with greater facility.

*Ought Dropsy to be considered a Disease?*—It has been said, with much truth, that dropsy is rather a symptom of disease than a disease itself; and that it would be more philosophical to treat of the original malady on which the accumulation of fluid depends, and to withdraw dropsy altogether from the class of substantive diseases. But there are considerations which entitle us to regard dropsy as still constituting a genus of diseases, and particular dropsies as specific forms of disease. For, allowing that dropsy is often or always a symptom, it is one which, in many instances, we cannot trace home during life, or satisfactorily ascribe to any organic change discoverable after death; so that, practically speaking, the dropsy in such cases is the disease and sole object of our treatment. Moreover, the liquid accumulation is a symptom very obvious and striking in itself, while it results from various physical alterations, differing both in their seat and in their nature; and it will be useful to study dropsies collectively;—if it be only with the view of analyzing them, and of referring them, as often and exactly as possible, to the pre-existent disease.

Dropsy is, in fact, to a medical eye, in all cases something more than an effect or symptom of disease. The fluid collection itself is a cause of various other symptoms;—of symptoms which often constitutes the greater part, or the whole, of the patient's distress and danger. The imprisoned liquid, by its weight or pressure, may embarrass important functions, or even extinguish life. The removal of the dropsy will frequently restore the patient at once to comparative comfort; or indeed to what, so far as his sensations and powers and belief are concerned, is for the time to him a state of health; although the original bodily cause, of which the dropsy was a symptom, may remain behind untouched;—to be again productive of similar consequences, under circumstances favourable to its operation. Sometimes it happens that the bodily change which is the immediate cause of the dropsy, is slight or temporary; while the patient's comfort, and very existence, are compromised by the mere accumulation of the water; and if this accumulation can be remedied by art, its temporary producing cause may cease, or be removed, or

admit of compensation; and so the patient may be strictly restored to sound health. In a dropsical person, then, whose dropsy results from organic disease, there are plainly two sets of symptoms to be distinguished; namely, those which depend upon the primary disease, and those which are caused by the collection of water. And these two sets of symptoms differ, perhaps, not only in their gravity and importance, but also in their obedience to treatment. The latter, usually the most grievous, may often be got rid of; the former are frequently but little complained of or felt by the patient, but are generally permanent.

Dropsy would perhaps be thought by many a more attractive subject, if it were not so commonly considered incurable. But the preceding remarks may suffice to show that, as far as itself is concerned, it often *is* curable; and some of its forms will hereafter appear to be curable in a more absolute sense;—the serous collection, and the condition from which it proceeds, both admitting of remedy. Besides: it is our business and aim to cure it when we can; and, whether we can cure or not, to remove or mitigate human suffering; and this we are able to do, to a very considerable extent, in many or in most cases of dropsy.

*Different Forms of Dropsy.*—Wherever there is a shut sac, or wherever there is loose and permeable cellular tissue, there we may have dropsy. Thus, there may be dropsy of the ventricles of the brain, or of the meshes of the pia mater,—producing death by *coma*; of the cellular tissue of the lungs, or of the submucous tissue of the larynx,—both leading to death by *apnœa*;<sup>a</sup> or of the pericardium,—causing death by *syncope*. Almost every mode of dying, therefore, may result from dropsical accumulations.

When the cerebral ventricles are distended with water, we express the diseased condition by the term "*hydrocephalus*." When serous fluid occupies the pleura, or the pericardium, we say the patient has *hydrothorax*, or *hydropericardium*. If the cavity of the peritoneum be the seat of the collected water, we call the complaint "*ascites*." When the cellular tissue of a part becomes infiltrated with serous liquid, the part is said to be *œdematous*; and "*anasarca*" is the name given to the more or less general collection of serum in the cellular tissue throughout the body, and especially to visible subcutaneous œdema of much extent. Under the term "*general dropsy*" we signify the simultaneous existence of anasarca, and of dropsy of one or more of the larger serous cavities.

Certain forms of dropsy—for example, dropsy of the *tunica vaginalis testis* ("hydrocele"<sup>b</sup>) and dropsy of the joints and bursæ ("hydrarthrus"<sup>c</sup>)—belong to surgery, and need only to be glanced at for the sake of elucidating the general subject.

## SECTION I.—GENERAL PATHOLOGY OF DROPSY.

Under what conditions, and by what mechanism, do the hollows and interstices of the body become thus filled and oppressed with water? In other words, what is the general pathology of dropsy? It is an ultimate fact, that from all the surfaces of the healthy living body there is continually going on a kind of secretion, or oozing forth of fluids. The inner surfaces of the shut cavities, and the partitions of the cells of the cellular tissue, furnish no exceptions to this law. If we examine the interior of an animal just slaughtered, or observe a cavity laid open in the human body, (by accidental injury,) we find that their inner surfaces are *moist*; and, indeed, we may see the fluid escape into the colder atmosphere, in the form of vapour. We perceive, also, that the surface is merely moist. The fluid in these shut cavities, during life and health, being taken back again into the circulating blood as fast as it exudes, the two processes of exhalation and absorption are accurately balanced. The disturbance of this equilibrium would account for dropsy.

<sup>a</sup> From *α* (privative) *without*; and *πνεω*, *to breathe*.

<sup>b</sup> From *ὕδωρ*, *water*; and *κνήλη*, *a tumour*.

<sup>c</sup> From *ὕδωρ*, *water*; and *αἰθρῖον*, *a joint*.

Now considering the matter hypothetically, we perceive that the balance may be deranged, and the dropsy arise, in one or both of the two following ways. Either the quantity of fluid exhaled may be over-abundant; or the amount of absorption may be deficient; or both these deviations from the natural state may occur together. It is obvious, that dropsy will ensue whenever the exhalation takes place faster than the absorption; and this may happen when both are in excess, or both defective. The inquiry may be reduced, however, in the first instance, to these two questions:—"Is there ever a preternatural amount of exhalation? Is there ever defect of the natural absorption?" An affirmative answer to either question, would *explain* the occurrence of dropsy. So, *à fortiori*, would an affirmative answer to both.

These inquiries being satisfied, another point would require to be investigated; namely, whether the product of the exhaling process may not be liable to variation in quality, as well as in amount;—whether the liquid actually accumulated in dropsy, is essentially identical with the liquid naturally exhaled. Are there, then, any known facts which accord with the hypothesis of a preternatural exhalation or pouring out of the serous liquid? There are; and in order to appreciate them, it will be necessary to bear in mind some further physiological truths. Reference has already been made to the perpetual separation of watery fluid from all the surfaces of the body;—the external, and those which communicate with the air, as well as the inner faces of the closed cavities. The fluids that exhale from the former class of surfaces are, for the most part, excretions. They are thrown out of the system; and, with respect to these, something more has been ascertained. It is observable, that when the escape of aqueous fluid from one such external surface is checked, exhalation becomes more copious from some other excreting surface or organ. And there are special sympathies of this kind established between certain secreting parts. It is probable that, so long as other circumstances remain the same, the aggregate amount of water thus expelled from the system cannot vary much, in either direction, without detriment to the individual,—manifested by symptoms. But we are sure that the quantity furnished by each secreting surface, may vary and oscillate within certain limits consistent with health;—provided the defect or excess be compensated by an increase or diminution of the ordinary expenditure of watery liquid through some other channel. Sound health admits and requires this shifting and counterpoise of work between the organs destined to remove aqueous fluid from the body. The sympathy, or compensating relation here spoken of, is more conspicuous with regard to some parts than others. The reciprocal but inverse accommodation of function that subsists between the skin and the kidneys, affords the strongest and the most familiar example. In the warm weather of summer, when the perspiration is abundant, the urine is proportionally concentrated and scanty. On the other hand, during winter, when the cutaneous transpiration is checked by the operation of external cold, the flow of dilute water from the kidneys is strikingly augmented. All this is well known to be compatible with the maintenance of the most perfect health. But supposing the exhalation from one of these surfaces to cease or to be diminished, without a corresponding increase of function in the related organ, or in any organ communicating with the exterior, then dropsy, in some form or degree, is very apt to arise. The aqueous liquid, thus detained in the blood-vessels, seeks, and at length finds, some unnatural and inward vent; and is poured forth into the cellular tissue, or into the cavities bounded by the serous membranes.

If water be injected, in some quantity, into the blood-vessels of a living animal, the animal soon perishes;—generally dying by coma, or by suffocation: and when the carcase is examined, the lungs are found to be charged with serous liquid; or water is discovered in the cellular tissue of some other part, or in the shut serous membranes. If, however, the animal be first bled, and then a quantity of water, equal to the quantity of blood abstracted, be injected, the injection is followed by no serious consequences.

It has been ascertained, that animals (dogs, cats, and rabbits) survive the extir-

pation of both kidneys for a space of time varying between ten hours and nine days. Copious and very liquid evacuations from the intestines, vomiting, and fever precede their death. Clear serum is found in the cavities of the brain, the bronchi are full of mucus, the intestines of liquid fæces, and the blood is more than naturally aqueous. So in the disease called "*ischuria<sup>a</sup> renalis*,"<sup>b</sup> the secretion of urine is suppressed; death by coma ensues; and the web of the pia mater, or the cerebral ventricles, are often found full of water. In cholera, there is suppression of urine for as long a space; but the brain is unaffected; for the system is drained of its water by the profuse discharges from the stomach and bowels. Conversely, in diabetes the skin is permanently dry;—the kidneys pour forth their altered secretion with a fatal prodigality.

The several classes of facts which have now been briefly brought into view, throw a strong light upon a confessedly obscure part of pathology. It appears that, in various circumstances, the blood-vessels may receive a considerable and unwonted accession of watery fluid; and that they are very prone to get rid of the redundancy. When they empty themselves through some free surface, their preternatural distension is relieved by a flux; if, on the other hand, the surface be that of a shut sac, in discharging their superfluity they cause a dropsy. Why sometimes *one* organ, and sometimes *another*, is selected as the channel by which the superabundant water shall be thrown out of the vessels, is a matter concerning which we can seldom render any satisfactory account. We often find it difficult to determine which of the two facts in question is to be considered the antecedent, and which the consequent. For not only is it true that, when the blood-vessels become overloaded with serous fluid, they readily deposit a part of it; but it is also true, that when they are in the opposite condition of comparative emptiness,—when they contain less blood than is natural, they are equally ready to replenish themselves by absorbing fluids from any source to which they can find access. In the case of an individual who was cured of his hydrocele upon the occurrence of profuse watery discharges from the stomach and bowels, it seems clear that the expenditure of serous liquid from one part, led to its absorption into the blood from another. When anasarca suddenly leaves the extremities, or ascites the abdomen, and fatal coma follows, it appears probable that the absorption is the first of the changes, and the effusion the second; and had this effusion been determined to the mucous membrane of the intestines, to the skin, or to the kidneys, it would have brought relief and safety to the patient, instead of causing his death.

We have obtained, then, a glimpse of one or two most important principles, with respect to the pathology of dropsy:—the blood-vessels, when preternaturally full of aqueous fluid, have a strong tendency to empty themselves; when preternaturally empty, they readily drink up watery fluid wherever they come into contact with it. From the discharge of their superfluity of water, arises a dropsy or a flux. The cause and the cure of many dropsies, lie in these propositions.

*Active Dropsy.*—The dropsies hitherto considered,—resulting from the rapid as well as preternatural pouring out of fluid by the blood-vessels,—compose an especial class of dropsies; in which the arterial system is more concerned than the venous; and to which the term "*active*" has sometimes been applied. For the sake of convenient distinction, and in conformity with established usage, we shall retain that epithet. But the number of these active dropsical effusions quite independent of inflammation, is small when compared with the whole number of dropsies. The state of the part from which the effusion proceeds, borders closely upon inflammation. The condition of its capillary circulation, has been regarded as intermediate between that in which the ordinary quantity of secretion is maintained, and that in which inflammatory effusion takes place. The increase of secretion is analogous to what we observe in other parts of the body;—to abundant perspirations, for example, that are occasioned by violent exercise; to the increased flow of tears caused by any irritation of the eye, or by the passion of grief; to the

<sup>a</sup> From *σχω*, to restrain; and *ουρον*, urine.

<sup>b</sup> From "*ren*," the kidney.

augmented watery discharges from the mucous membrane of the bowels, produced by purgative drugs;—all of which may be independent of inflammation, but all of which are attended by congestion, that may easily be pushed into inflammation; and it is obvious, that if the secretions just referred to were poured forth into closed cavities, instead of proceeding from surfaces that are situated on the exterior of the body, or communicate readily with the exterior, they would constitute dropsies.\*]

*Inflammatory Dropsy.*—By far the larger number of those dropsies that are called “active,” are of an inflammatory character; and require to be treated, not by diuretics, but simply by the remedies of inflammation. In the arachnoid, the pleura, and the pericardium, for instance, dropsy is frequently attended with the most decided inflammation, both acute and chronic. Sometimes, though not so frequently as in the cases just mentioned, we see dropsy in violent inflammation of the abdomen; but very often ascites itself is a decidedly inflammatory disease. In such cases, the usual signs of inflammation of a serous membrane occur. When the affection is situated in the arachnoid, we have pain of the head, intolerance of light, perhaps squinting, and great quickness of pulse. In inflammatory dropsy of the pleura, pain in the side, dyspnoea, and cough, form conspicuous symptoms. With respect to the pericardium, we have pain in the region of the heart, perhaps a rapid pulse, palpitation, and pain darting from that organ in various directions. In the case of the abdomen, the pain is considerable, and is increased on pressure. All these affections are of an inflammatory character, and tend to induce more or less effusion in every case; but occasionally the effusion is very considerable; and then the word “*dropsy*” is applied to the collection.

*Passive Dropsy.*—[A much larger class of dropsies commence in defective absorption. There is no sudden and profuse gush (as in the former class) from the overlaid blood-vessels; but the fluid which is healthfully and unceasingly exhaled from the serous surfaces, fails to find its way back again into the blood, and gradually accumulates. The mechanism of the morbid process is commonly as follows:—Some cause retards the current of venous blood: hence the veins, and the capillaries by which they are fed, become distended; and this distension constitutes an impediment to the further admission of liquid. Absorption is sluggish, or at a stand. To dropsies thus originating, we give the name of “*passive*.” The venous system is more concerned in them than the arterial.

But we have still to show more clearly, that dropsies may and do originate in this manner. The agency of the blood-vessels in the production and removal of dropsy, has not been sufficiently recognised till of late; or perhaps it should rather be said, that more importance used to be assigned to the agency of the lymphatic absorbents, than they are really entitled to. Pathologists, even of recent date, speak of a want of tone or energy in the absorbing vessels—of the superfluous fluid of the part not being adequately taken up by the enfeebled absorbents;—meaning, thereby, the absorbents properly so called. And this view of the matter—connecting dropsy always with debility as its cause—has infected the whole pathology of the disease, and led to a corresponding mode of treatment;—the object aimed at being the stimulation of the absorbents to more vigorous action. This obvious difficulty, however, presents itself at once to the theory, that dropsy results from deficient activity of the absorbents: namely, that absorption goes on, and to a very great degree, in dropsical patients. Their adipose matter disappears;—they get miserably thin. There is no complaint in which emaciation goes to a greater extent than in dropsy. It is found, also, that persons afflicted with anasarca become readily enough affected by mercury; which, of course, must be absorbed before it can produce any of its specific effects.

*Physiology of Absorption.*—It must be confessed, that our knowledge respecting absorption is neither complete, nor absolutely certain; but there appears good reason for supposing, that the process is shared between the lacteals, the lymphatics, and the veins; and, probably, somewhat in this manner:—that the lacteals absorb the

\* “Library of Medicine;” Volume 5; Pages 97 to 101.

chyle from the surface of the intestines, and convey into the blood the materials for its renovation; that the office of the lymphatics is to take up and carry into the blood, that effete portion of the solid constituents of the body which requires to be removed, to make way for a fresh deposit; while the veins imbibe the serous fluid exhaled from the surfaces of serous membranes, and into the meshes of the cellular tissue, as well as poisonous and other substances that are soluble and dissolved in that fluid.

Now, if this be so, one of these last sets of absorbing vessels,—the lymphatic apparatus or the venous,—may continue to perform its office, while the other fails to do so. This theory is sufficiently consistent with the actual phenomena of dropsical disease; and, whether it be altogether true or not, a part of it is certainly true;—that, namely, which assigns to the veins a large share in the whole process of absorption. The experiments of Magendie, Fodéré, and others, are quite conclusive upon that point. It has been proved, that fluids may pass into and out of the veins through their parietes, independently of any vital process, and by mere physical imbibition and transudation; so that when the veins are distended to a certain point with watery fluid, the introduction of more of the same fluid through their coats is impeded or prevented; and when the distension is still greater, the aqueous part of the blood may even pass, in the other direction, out of the vessel. On the other hand, when the veins are comparatively empty, the serous fluid passes readily into them; or, in common language, is absorbed. Venous absorption is explicable, therefore, upon the principles of endosmose and exosmose,—as laid down by Dutrochet; or rather (according to professor Daniel's happy generalization of Dutrochet's facts) by the theory of heterogeneous attraction. Imbibition, being a form of that attraction, belongs in various degrees to all the tissues of the body. Its rapidity, and even its direction, with respect to the sides of a vessel surrounded by fluid, and also carrying fluid of a certain consistence, must vary with the varying distension of the vessel. When the vessel is moderately full, the exterior fluid passes uninterruptedly inwards, and is conveyed away by the internal current. When, on the other hand, the vessel is much distended by its contents, the contained fluid, or its thinner part, passes continually outwards. And there is an intermediate degree of distension, at which the pressure is just enough to prevent the transit of fluid in either direction. Magendie found, accordingly,—in an ample, well conducted, and conclusive series of experiments,—that by regulating the conditions of comparative emptiness or fulness of the circulating system, he could accelerate, retard, or altogether suspend the operation of a poison dissolved in the humours of the body. In other words, he could thus accelerate, retard, or prevent the process of absorption or imbibition through the blood-vessels. If we are once satisfied of the absorbing and transmitting property of the sides of the vessels, we shall have no difficulty in perceiving how any mechanical obstacle, occurring in a venous trunk, may give rise to dropsy.

Having then deduced, from physiological data, that dropsy may occur from mechanical obstruction in any of the larger venous trunks, let us, in the next place, ascertain whether, in point of fact, it ever has this kind of origin. The truth of this was first determined, experimentally, by our countryman Dr. R. Lower; who, though these experiments were not instituted with any reference to the pathology of dropsy, perceived their bearing upon that subject;—as appears from the following remark:—"Quantum hæc ad ascitis et anasaræ causas investigandas conducant, aliis judicandum relinquo."<sup>a</sup> In one of these experiments, he applied ligatures to the jugular veins of a living dog; in two days the dog died; and the cellular tissue about the head and face was found to be distended, not with blood (as Lower had anticipated), but with clear and limpid serum. In another experiment, he tied the *vena cava* just after it emerged through the diaphragm; in a few hours the animal died; and a large quantity of fluid, precisely similar to the fluid of ascites, was found in the peritoneal sac. These results have been confirmed by more modern

<sup>a</sup> "Library of Medicine;" Volume 5; Pages 101 to 103.

and conclusive experiments; and afford a satisfactory explanation of nearly every form of local dropsy, or even general anasarca.<sup>a</sup>]

*Dropsy from Obstruction.*—As in many cases of hæmorrhage the flow of blood proceeds from mechanical obstruction, so does the same occurrence take place in dropsy. If great obstruction take place in any of the veins, dropsy must be the consequence. Local, and more or less extensive plethora take place, in all the vessels on the other side of the obstruction. As a mere physical effect, the watery parts of the blood ooze forth from their extremities; and the part becomes more or less turgid,—from the great serous congestion. There is every reason to believe, that the swelling of the leg after parturition, called “phlegmasia dolens,” depends upon mere mechanical obstruction. There is more or less œdema of the leg; and it usually arises (according to Dr. D. D. Davis and others) from obstruction.<sup>b</sup> There is an obstruction of the veins at the upper part of the extremity; and perhaps, also, in the veins still higher up. The pressure of a very enlarged womb will often, in this way, induce dropsy of the lower extremities. In cancer affecting the axillary glands, or when the breast is attacked by cancer or scirrhus, an upper extremity becomes œdematous;—simply from mechanical obstruction. It is not necessary that the absorbents should be affected; for if the veins be obstructed, the same effect is produced. A local plethora takes place;—both of veins and capillary vessels. These pour forth a watery secretion; and dropsy is sure to occur at last;—simply as a mechanical effect.

If the obstruction occurs at that point where all the veins of the body meet, anasarca of the universal cellular tissue, and an accumulation of fluid in all or most of the serous cavities, supervene.

*Dropsy from Debility.*—It frequently happens, however, that general dropsy arises from debility. The patients are exceedingly pale, with a very weak pulse, and extreme debility of the whole frame. In these cases, the more they are weakened, the worse they become;—the more does the dropsy increase. When there are no signs of inflammation,—no fulness of pulse (for there may be quickness without fulness), but (on the other hand) debility, and when the powers of the patient are becoming exceedingly reduced, the disease must be put upon a footing with passive inflammation, or passive hæmorrhage, or a passive discharge, —a gleet from a mucous membrane; and every thing which debilitates the body will make the matter worse. This will be the case if the dropsy arise from visceral disease; such as disease of the liver,—a liver full of tubercles, or indurated; scirrhus, or carcinoma of the womb; or ulceration of the lungs.

[But, independently of debility arising from organic disease, dropsy may arise purely from debility of the heart;—producing a serious retardation of the venous circulation. We see this every day in weak, chlorotic girls, with bloodless cheeks and pale lips. Such persons have weak and flabbily voluntary muscles; and it is reasonable to presume that the involuntary muscles (of which number the heart is one) should partake of the general feebleness of the muscular system, and become incapable of performing their office with proper energy.

Nay, it is credible and likely, that a feeble heart may in these circumstances yield a little, and dilate under the resisting pressure of the blood which enters its chambers; and that, in this way, the occasional but temporary bellows-sound may arise;—in consequence of the altered relation between the cavities of the heart and their outlets. And the *juvantia* and *lædientia* confirm this view of the matter. If, tempted by the pain complained of by the patient, or by the violence with which her overtasked heart is throbbing, we take away blood, we find that, whatever present relief she may experience, she is ultimately weakened by the depletion. On the other hand, if we give her steel, feed her well, and administer the cold shower-bath, we find that she regains her lost strength;—that colour returns

<sup>a</sup> “The bearing of these investigations on the causes of ascites and anasarca, I leave to the judgment of others.”—“*Tractatus de Corde*,” by Richard Lower, M.D.; 1669; Page 82.

<sup>b</sup> It is, however, the belief of more recent pathologists, that there is, in addition to the obstruction, a peculiar inflammation induced in the casts of the affected veins;—having no tendency, like common phlebitis, to spread.

to her lips and cheeks, her palpitations cease, and her dropsy departs. In proportion as the muscular system in general receives fresh tone and vigour, does that particular muscle, the heart, recover the degree of power necessary for the effectual discharge of its proper function; which is very much that of a forcing-pump. Such is the way in which we would explain both the dropsy and its cessation. In such cases our patients do not simply recover;—they are cured; and we would apply the same explanation to some other forms of dropsy. Andral describes a certain cachectic condition of the body, as being a cause of dropsy;—persons may be bled into a dropsy, and starved or weakened into a dropsy. These are genuine instances of dropsy from debility;—such as the ancients conceived all dropsies to proceed from. It may be that the thin or watery condition of the blood,—induced by frequent bleedings, by insufficient nourishment, by poisons, or by other causes,—may facilitate its escape through the sides of the vessels; but it seems more probable, that all dropsies arising in the circumstances just referred to, and without any apparent organic disease or change, are mainly, if not entirely, to be ascribed to debility of the heart; and, viewed in this way, they are all brought under the same general principle; namely, the retardation of the blood in the veins, and the consequent preternatural fulness of the blood-vessels. All passive dropsies, at least in our opinion, may ultimately be referred to this principle. This principle being once admitted, several other phenomena, which could scarcely be adduced in proof of its soundness, may find in it their explanation, and thus serve to confirm its truth. Persons of a full habit are observed to perspire readily and profusely; and it is asserted, that if such persons are bled, the tendency to perspiration either yields entirely, or is sensibly diminished.

*Different Forms of Dropsy Contrasted.*—In the preceding remarks, extreme cases have been taken to elucidate the two classes of dropsy, that have been respectively denominated “active” and “passive.” It may help towards a clearer notion of the pathology of which we are in search, if we contemplate the points of resemblance and the points of distinction between the two forms. They resemble each other in the result; namely, in the collection of serous liquid in the circumscribed cavities and vacuities of the body. They differ in the rate at which the collection augments.

In well-marked acute cases the liquid is rapidly effused, in quantity much exceeding the natural amount of exhalation. In well-marked chronic cases, the exhalation goes on as usual; but the fluid exhaled is not taken back again into the circulating vessels with sufficient facility. In the one case, the circulation is disturbed and tumultuous; in the other, it remains tranquil. It is probable that, in the more acute forms, the serum passes through the coats of the arteries, or of the capillary vessels next adjacent to the arteries. In the completely chronic form, there is a defect of absorption by the veins.

But there are intermediate degrees, in which it appears that the full veins are not only unable to admit a new supply of aqueous liquid, but also to retain that which they already hold; and serosity exudes from them also.

What connects all these forms of dropsy, is a preternatural fulness in some part, or the whole, of the hydraulic machine. And this seems to be the great key to the entire pathology, as well as to the remedial treatment, of the disease.<sup>a</sup>

*Characters of the Fluid.*—With regard to the fluid of these various dropsies in the chest (the pleuræ and the pericardium), in the peritoneum, and in the head, it is sometimes perfectly clear; but more frequently it is at least turbid;—not transparent, though translucent. Sometimes it is very turbid indeed; and sometimes bloody. The fluid which forms the swelling, in anasarca, is perfectly clear; as is proved by the operation of acupuncture. If we make a minute puncture of the skin, with the point of a needle, (which is acupuncture,) a bead of fluid, beautifully transparent, follows. In the case of chronic dropsy within the head,—chronic hydrocephalus,—the collection of fluid is almost like rock-water. In chronic

<sup>a</sup> “Library of Medicine,” Volume 5; Pages 105 to 107.

hydrocephalus, more frequently than otherwise, the fluid is collected within the ventricles of the brain; and this fluid is very little different from pure water. It contains the least possible quantity of animal matter and salts. I believe the fluid of chronic hydrocephalus comes nearest to pure water, of any fluid that is morbidly collected in the body.

*The Fluid sometimes Shifts its Place.*—The swelling, of course, is most considerable where gravity directs the fluid in the greatest quantity; so that any part which is dependent, becomes much more swollen in consequence; and we may regulate the swelling, by regulating the posture of the part. But sometimes the swelling will shift, independently of any particular position. Where a person is lying straight in bed, one day one arm will be swollen, and the next day the other. Sometimes it will shift to the leg, and then return to the arm again. This is a remarkable circumstance; but one that does occur continually, without any connection with posture.

*Prognosis.*—I did not mention any particulars for forming a prognosis, in cases of hæmorrhage, or in the case of the various fluxes; because the prognosis is only to be made by observing the degree of disturbance on the one hand, and the strength of the patient on the other. In dropsy, we must of course follow the same rule; but as dropsy, when it is not inflammatory, so frequently depends upon organic disease, our prognosis will depend, in a great number of cases of a chronic character, upon the evidence which there is of organic affection. We have also carefully to note, in giving a prognosis with regard to dropsy, whether, although the dropsy improves, some other symptom does not continue or get worse. Dropsy will sometimes diminish rather suddenly; and the patient, so far from being better, (although that is apparently the case,) will die within a very short time. Sometimes, a short period before death, all the external symptoms of dropsy have diminished. Sometimes ascites will nearly disappear, or greatly improve at last; and œdema of the legs and the whole body diminish very considerably; and yet the patient will speedily die;—perhaps of apoplexy, perhaps of effusion into the chest. We must not be satisfied with the disappearance of any of the symptoms of dropsy. We must also carefully observe whether there are not still sufficient symptoms of mischief within, to make us fear the result of the case. Very frequently the severest symptoms may still exist; and may soon exhibit the most dangerous character, after a dropsy has spontaneously diminished.

Having now given a sketch of the general pathology of dropsy,—let us, in the next place, trace out the peculiar features of each of its leading varieties.

## SECTION II.—ACUTE OR FEBRILE DROPSY.

Anasarca frequently exists alone, as an acute febrile dropsy; sometimes as a chronic affection;—without, however, any indication of organic disease during life; though perhaps, after death, we may find extensive organic disease of the kidney or heart.

*Signs of Febrile Dropsy.*—When dropsy occurs in the cellular membrane,—that is to say, when it contains a preternatural quantity of fluid,—we have a white, soft, and inelastic swelling of the surface; which swelling pits upon pressure. The swelling may sometimes be red; because the skin may become inflamed, as well as the cellular membrane beneath. It sometimes is not soft, but intensely hard;—owing to the high degree of inflammation of the cellular membrane, and the fibrinous nature of the effusion.

When this dropsy of the cellular membrane is sudden and febrile, it generally is more apparent in the face, than anywhere else; and I believe the reason to be, that it generally arises from cold, and the cold is more frequently applied to the face than any other part. Usually, when these collections take place,—wherever they may be seated,—the urine is scanty; but when the cellular membrane is the seat of the affection, and the affection is of an inflammatory nature, it is very common to

see the urine of its natural quantity;—nay, very frequently, I have seen it more than it should be.<sup>a</sup> If we inquire into the state of the head, we commonly find that the patient says it is heavy;—perhaps he has violent pain there; but generally it is heavy. If we press the abdomen, we frequently find tenderness; but, above all, there is generally an inflammatory state of the chest. The patient complains either of pain in the chest or of cough; or if the naked ear, or the stethoscope, be applied to the chest, either the sonorous or sibilous rattles of the bronchia will be detected; or the crepitous rattle which indicates inflammation of the air-cells.

*State of the Pulse.*—The pulse, in dropsy of the cellular membrane, is frequently hard and full; and it is from the occurrence of the local symptoms of inflammation in the head, chest, or abdomen; from the strength of the pulse; from the suddenness of the occurrence of the dropsy; together with the nature of the causes which have produced it, being such as produce inflammation; it is from these circumstances that we judge the disease to be of an inflammatory kind.<sup>b</sup> For, although the affection is so decidedly inflammatory, the cellular membrane is not tender. Patients, in general, do not complain of pain, when pressure is made on the surface of the body. Yet the inflammatory nature of the disease is sufficiently shown by the relief experienced on free bleeding, by the buffed and perhaps cupped state of the blood, and by the nature of the causes which produced the disease. The local inflammation that exists within the head, lungs, or abdomen, may generally account for the buffy state of the blood, and the relief that is experienced by bleeding; but when the dropsy itself ceases so rapidly as it does after bleeding, it is impossible not to believe, that the dropsy itself was of an inflammatory kind.

*Causes.*—This inflammatory dropsy of the cellular membrane, more frequently arises from cold and wet, than from any other cause; whereas inflammatory effusion into the arachnoid, pleura, pericardium, and peritonæum, may or may not arise from that source. I hardly recollect a case of dropsy of the cellular membrane, of an inflammatory kind, which did not arise from cold and wet; and it is generally accompanied by inflammation of some internal part; or, if not by inflammation, at least by an inflammatory state. Perhaps it is combined with an inflammatory state of the head;—not with decided phrenitis; but with heaviness, giddiness, and pain. Sometimes it is united with an inflammatory state of the abdomen; but, as far as I have observed, it is much more frequently combined with an inflammatory state of the lungs; either in the form of bronchitis (which is by far the most common) or of pneumonia.

The more chronic kind of dropsy, which appears independent of inflammation, is sometimes united with, and is one of the last symptoms of, structural disease of an internal organ. In disease of the heart, it is very common for a person to become dropsical. In a large number of instances of phthisis, there is œdema of the legs, towards the conclusion of the affection; and when the liver, the uterus, or

<sup>a</sup> In febrile dropsy, the urine is scanty, deep-coloured, brown, and more or less turbid, like muddy beer. It is full of albumen, also; and its specific gravity is somewhat diminished. Often it deposits a brownish or black sediment,—consisting of small black grains; and sometimes it is red;—either appearance evidently resulting from an admixture of the colouring matter of the blood, more or less changed in its characters. These, indeed, are the phenomena that constitute the link of alliance between febrile and renal dropsies.—“*Library of Medicine*,” Volume 5; Page 131.

<sup>b</sup> If the serous fluid be the product of inflammation, what is the part inflamed? It cannot be the distended cellular tissue itself; for if so, the inflammation must shift its quarters under the influence of gravity. We are far from denying the frequent agency of inflammation in producing changes which, in their turn, lead to dropsy; but it will be well not to confound those collections of serum mixed with blood or coagulable lymph, which are distinctly events or products of inflammation, with other collections of serum which resemble the former in that respect only, but differ entirely from them in every other particular. To those cases of dropsy occurring suddenly from obstruction of one or more of the usual channels of aqueous excretion, and which are usually attended with considerable disturbance of the whole system, the epithet “*febrile*” would not be inappropriate; though the hot and dry skin, thirst, flushed cheeks, full and hard pulse, and furred tongue, render it necessary, practically, to regard it as an inflammation.—T. Williams.

the spleen is diseased, dropsy is exceedingly common. But anasarca, as only one form of dropsy, often follows others. When a person has fluid in the cavity of the pleura, it is usual for the legs, and perhaps the whole body, to become œdematous. When there is effusion into the peritoneal cavity, it is very common for this *ascites* (as it is called) to be, sooner or later, followed by œdema of the lower extremities; and at last the effusion may become general, and constitute anasarca.

All these particular dropsies closely resemble hæmorrhage and fluxes. Hæmorrhage and fluxes, as already mentioned,<sup>a</sup> are frequently of an active inflammatory kind; and are to be treated, not by remedies calculated to arrest the flow of fluid, but by the remedies of inflammation;—not by astringents, but by antiphlogistic measures. On the same principle, inflammatory dropsy is to be treated, not by remedies calculated to carry off the fluid, or stop up the mouths of the vessels which pour forth the secretion, but by remedies calculated to remove inflammation.

*Renal Disturbance.*—[That the functions of the kidneys—which are, in so great a measure, complementary of the functions of the skin—should sustain a proportional derangement, is what we might expect; and the altered qualities of the secretion—the bloody or albuminous condition of the urine—testify, invariably, the strain which these organs undergo. Sometimes, though not often, death is the early result of the attack; and it is usually preceded by an extreme deficiency, or an absolute suppression of the urinary secretion, and by coma. In all the fatal cases of febrile dropsy that have fallen under our observation, the kidneys have been found large, of a dark chocolate or purplish red colour throughout;—turgid with blood, that seemed to be venous. We regard these appearances as being evidences of excessive congestion, rather than of inflammation; because neither the ordinary and striking symptoms of nephritis, nor the unambiguous products of inflammatory action, are usually observed in such cases. We have been informed however, upon good authority, of one instance in which coagulable lymph was found effused in the pelvis of the kidney.

When the disease does not prove fatal at once, the dropsical and other symptoms give way;—either spontaneously, or under the treatment to be hereafter described. But there is much reason for thinking that, unless the overcharged system be speedily relieved, the germ of future and progressive disorganization of the kidneys may be sown. “Febrile dropsy,” and “acute renal dropsy,” may be considered, without much risk of error, as convertible terms.<sup>b</sup>]

### SECTION III.—RENAL DROPSY.

Having, thus far, shown that febrile dropsy is intimately connected with a disturbance of the renal function, we shall next proceed to the consideration of that form of dropsy, which arises from organic disease of the kidney, and to which the term “*renal dropsy*” has been specially applied. The following are the chief indications which guide us in the diagnosis of these cases:—1. The absence of any direct symptoms of cardiac disease. 2. The complexion of the patient. 3. Occasionally, certain parts of his previous history. 4. Certain conditions and qualities of the patient’s urine.

The morbid conditions on which this form of dropsy depends, have been pointed out by Dr. Bright; to whom, indeed, we owe most of our knowledge on this subject. They relate to the size, figure, and consistence of the kidney; and also to the colour and consistence of its surface and interior.

#### *a. Morbid appearances of the Kidney.*

*Size and Weight.*—[The size of the kidney varies greatly. The average weight is about four ounces. M. Rayer has met with some kidneys, in this dis-

<sup>a</sup> See Pages 139, 144, and 145.

<sup>b</sup> “Library of Medicine,” Volume 5; Page 132.

ease, weighing twelve ounces. The increment and the decrement of the natural bulk belong principally, if not altogether, to the outer secreting portion of the gland. If a longitudinal section of an exaggerated kidney be made, the cortical part is seen to be unduly broad; and the same part is evidently narrow when the whole organ is smaller than common. For this reason, in the latter case, the radiating medullary parts approach nearer to the surface than they are observed to do in a healthy kidney. Furthermore: it would appear that the enlargement is most commonly coincident with the earlier, and the contraction or shrinking with the later, periods of the renal disease.

*Consistence and Form.*—The *consistence* of the diseased gland is also variable. Sometimes, and for the most part in the earlier periods, it is soft and flabby; sometimes, and especially in the later periods, it is remarkably compact and hard. The size and the consistence of the kidney may be said to be, in most cases, inversely proportional to each other. Again: the *form* of the kidney, in the disease in question, often undergoes some modification. As the special change proceeds, the exterior of the gland shows a tendency to become indented by linear depressions, and to present a lobular shape. This, however, is by no means a constant phenomenon, even in the most advanced stage of the malady.

*Colour and Condition of its Surface.*—When the proper investing tunic is stripped off, and less distinctly through the same tunic before its separation, the surface of the kidney appears mottled, marbled, or stained; of a yellowish gray colour in one place, and of a dark or purple tint in another; occasionally it is pale throughout its whole extent; more commonly of divers hues, and variegated with little streaks; which are portions of veins containing red blood. Sometimes the surface is curiously speckled; often uneven, as if strewed with prominent grains; and, in some instances, quite rough and scabrous. These several appearances are usually the more conspicuous, in proportion as the complaint is the more advanced.

*Appearance of the Cut Surface.*—The most uniform and characteristic of the morbid appearances, however, are those presented by the cut surface of the kidney, when it has been divided into two symmetrical portions by a longitudinal incision. We then perceive that the cortical substance is the main seat of the morbid alteration. It has lost in a greater or less degree, or sometimes almost entirely, its natural red colour and uniform aspect; sometimes it puts on a speckled or granular appearance; but this, in our experience, is less common than a pale homogeneous surface, streaked in general by linear marks; and bearing, when well pronounced, a near resemblance to the section of a painsnip. The view of the incised surface conveys to an observer the notion of some deposit having taken place; whereby the natural texture of the part is obscured, and its blood-vessels are (many or all of them) emptied or obliterated; while the healthier medullary masses are displaced and pushed aside,—sometimes compressed and encroached upon,—sometimes exhibiting the same yellowish appearance interposed between, and opening out, their radiating striæ. In several instances, along with these changes of appearance and structure, we have found the veins that emerge from the kidney blocked up by firm coagula of blood.

*Cysts.*—The kidney, in some rare cases, is studded, both on its surface and throughout its interior, with numerous small cysts or cells containing a thin transparent fluid. These cysts have been inaccurately called “hydatids.” It is not at all uncommon to meet with one or two such cysts in this diseased state of the organ.

*Sanguine Congestion.*—There is still another state of the kidney very different, in its appearance, from any that have yet been mentioned; which is thought however to be in some cases, if not always, the first stage of all in the disorganizing process. Without prosecuting for the present the inquiry how far this notion may be founded in truth, we shall describe the state in question. It may be briefly expressed in two words;—“*sanguine congestion.*” The whole organ is gorged with blood; which sometimes drips freely from it when it is cut open. The kidney

is in general somewhat flabby, of a deep and dark red, even of a chocolate or purplish colour, nearly uniformly diffused; except that the exposed surface is usually diversified by still darker tuft-like spots, which have been ascertained to be the Malpighian bodies filled with blood.

### *b. Signs of Renal Dropsy during Life.*

Let us in the next place investigate those circumstances which, during the lifetime of the patient, conduce to the conclusion that the dropsy under which we see that he labours is renal.

1. There is nothing, that we are aware of, very peculiar or distinctive in the characters of the anasarca itself. When the renal disease sets in suddenly and with acute symptoms, dropsy usually supervenes soon. So also, during its more chronic progress, anasarca is apt to show itself, or to increase, whenever inflammation of any part, or febrile disturbance, may happen to ensue. The more rapid and copious the effusion, the less do the dropsical parts pit upon pressure. Of this renal form of the disease it may also be stated, that an accumulation in the larger serous cavities is not, in general, a prominent feature.

2. We naturally look, in a case of general dropsy, for evidence of disease in the thorax, especially of the heart; and, most particularly, of retarded circulation in the veins. If we find no material or adequate embarrassment of the respiratory functions, no deviation from the natural sounds of the heart, no derangement of its regular movements, no alteration in the force of its pulsations, or in the space over which they may be heard and felt, no distension of the large veins of the neck,—we then have reason to suspect, at least, that the anasarca is connected with some vitiated state of the kidney.

3. Again: our judgment is guided or assisted, in some degree, by the complexion of the patient. When general dropsy depends upon disease of the heart, the cheeks and lips are occasionally florid, often purplish or livid, frequently dusky and loaded: sometimes the face and mucous membranes are pale (as in chlorotic women, where the heart may be temporarily distended without any strictly organic disease, and the blood is thin and poor): but, in the renal variety of dropsy, there is commonly a strikingly characteristic hue—an evident want of red blood, indeed, in the capillaries; but an unhealthy, dingy sallowness withal;—an aspect such as reveals, to an experienced eye, the existence of some visceral disease in the abdomen.

4. Our suspicion that the kidney is the organ in fault, is strengthened if we trace certain accidents in the history of our patient;—an attack of illness, for example, attended perhaps with temporary swelling of the body and disturbance of the urinary functions (acute dropsy, in short), soon after some exposure, in unfavourable circumstances, to the influence of cold, either applied to the external surface, or to the stomach by a draught of cold drink. For there is reason to believe, that in acute dropsy is often laid the foundation of those peculiar changes in the kidney, which, since they were first pointed out by Dr. Bright, have been chiefly studied in their connection with chronic dropsy;—that as rheumatic carditis may occur, and become latent as to its effects for some time, and yet implant the germs of future cardiac dropsy, so the stress or strain (of whatever nature it be) that befalls the kidney, in cases of febrile dropsy, may set on foot a morbid process which long works silently and unobserved; but which, at last, gives notice of its operation by symptoms;—the reproduction of dropsy in a more chronic form being the most significant symptom of all. The acute attack may have been forgotten; there have been no obvious (though there may have been ill understood) indications of the renal affection; and its existence has been unsuspected.

The previous history of intemperate habits, also, would be of importance in aid of our diagnosis, if these same habits had not a like influence in causing disease of other organs as well as the kidneys, and especially of the heart. There may, however, be no such episodes as these in the history of the patient: the dropsy may have come on immediately after some exposure or obviously injurious

influencee; yet not with acute symptoms, and in a temperate subject: in which case it is probable that the renal disease had pre-existed in a latent state; or the anasarca may have arisen by degrees, and without any apparent exciting cause. Suppression of the catamenia, and blows on the loins, have each been precursory of this form of dropsy, sufficiently often to raise a suspicion that the change in the kidney has been somehow a consequence of these accidents.

5. The most remarkable and sure evidence of the existence of the renal disease, is to be found in the state of the urinary secretion. Some of the characteristic qualities of the urine are very obvious, or easy of detection when sought for; others require for their discovery some little chemical knowledge and skill.

### *c. Characters of the Urine in Renal Dropsy.*

The more obvious characters of the unhealthy urine relate to its quantity, its sensible qualities, the presence of albumen, and its specific gravity; and, because they are obvious, these are the circumstances which, for the generality of practitioners, are of chief importance, and most require to be attended to and understood.

*Its Quantity.*—The quantity of urine secreted in this disease of the kidney, is inconstant. It always falls short of the ordinary standard, in the outset of the dropsy. In the acute cases, also, and whenever febrile symptoms supervene in the chronic, it is invariably diminished; and by this deficient expenditure of aqueous fluid through the kidneys, while the exhalation from the surface is also scanty or annulled (as in most instances it is found to be), may be explained, in great part, the occurrence of the dropsical accumulation. As the disease advances, the urine often returns to its natural amount; and not unfrequently is secreted in excess.

The average quantity of urine voided in the twenty-four hours, by a healthy adult, has been variously estimated. It may safely be put at about two or two and a-half imperial pints; that is, from forty to fifty fluid ounces. Sometimes in the disease in question it does not exceed one or two ounces, or is even suppressed altogether; and when this is so, the patient must be considered in imminent danger of some fatal affection of the brain. More generally, the patient voids from half a pint to a pint and a half of urine daily. In certain cases, or in certain stages of the disease, and chiefly in the advanced stages, the quantity may reach four or five, or even six, pints daily. These observations are to be understood as having no reference to the effects of diuretic medicines.

It may be stated as the rule, that the dropsy lessens as the urine becomes more copious, and contrariwise. But to this rule there are numerous exceptions. The dropsy may even augment while the quantity of urine is increasing. In such cases, other agencies are probably in operation besides the mere kidney-disease;—such as debility of the muscular parietes of the heart, engendered by the disease; or an altered and more aqueous condition of the blood;—to be more particularly described hereafter.

Whenever we find anasarca steadily persisting, or perhaps extending, while the quantity of urine (uninfluenced by diuretics) exceeds the average proper to the patient, we have reason to suspect the dropsy to be renal. The same phenomenon is, however, sometimes to be observed in the cardiac form of the complaint; as well as in the anasarca that occasionally supervenes in the latter stages of diabetes.

*Its Sensible Qualities.*—The sensible qualities of the urine are variable also, and differ at different periods of the disorder. Often it is dingy and dark-coloured, —brown, like slightly turbid beer; sometimes it is distinctly, sometimes obscurely, tinged by the colouring matter of the blood; frequently it deposits a dark-brown or soot-like powder; which is evidently composed of the coloured particles of the blood, changed in appearance, and probably blackened by the acid in the urine. Often, also, the urine is of a pale hue, not quite transparent, hazy, exhaling but little of the characteristic smell of healthy urine, frothing readily, and long retaining its head of froth. This depends on the copious presence of an unusual ingredient;—to be presently mentioned. Sometimes, but not very frequently, the urine

throws down more or less of the common lateritious sediment, and paints the bottom of the vessel pink. Sometimes, again, the secretion does not deviate materially, or appreciably, in its appearance from that which belongs to health. Of these several appearances, that which manifestly arises from the admixture of a greater or less quantity of blood, is most to be relied on as indicative of the renal disease. It is most common in the early stages of the dropsy; and in the acute variety these sanguineous impregnations are rarely, if ever, absent.<sup>a</sup>]

*Presence of Albumen.*—A still more important quality of the urine, in these cases, is the presence of albumen; and we have been told that our guide for bleeding in dropsy,—that our guide in forming a judgment as to whether it is inflammatory or not,—is to be taken from the appearance of the urine. It has been stated in a work published by Dr. Blackall, that the quantity and firmness of the coagulum of the albumen, is usually proportionate to the existence of inflammation, and to the necessity for carrying into practice anti-inflammatory means; but that nevertheless albuminous urine may, in some cases, be associated with an opposite state,—that of debility,—where the use of tonics is clearly indicated. Subsequent writers however, more especially Drs. Bright and Christison, have corrected the results of, and added much to, the original observations of Dr. Blackall.

[While Dr. Christison directs attention to the different *appearances* of the coagulum of albumen, he does not appear inclined to refer them to any variation in the intensity of the inflammation. At the same time, he proposes a very scientific nomenclature for the different degrees of coagulability shown by albuminous urine when subjected to heat:—1. Gelatinous by heat. 2. Very strongly coagulable;—the precipitate separating by heat, and in twenty-four hours occupying the whole fluid. 3. Strongly coagulable;—the precipitate occupying half the volume of the fluid. 4. Moderately coagulable. 5. Slightly coagulable. 6. Fully coagulable. 7. Hazy by heat;—where the urine becomes cloudy, but does not form visible flakes a few seconds after being boiled.<sup>b</sup>]

*Method of Detecting Albumen.*—[Its presence may be established by the majority of re-agents, which serve for its detection in pure water. The combination of the three characters,—coagulability by heat and nitric acid, and its *non*-precipitation by acetic acid,—affords alone incontestible evidence of the presence of albumen. But these three characters must co-exist;—since a mistake might arise from the circumstance, that urine containing milk will coagulate with heat and nitric acid; but, *unlike* albuminous urine, will also coagulate on the addition of acetic acid. When the urine contains *alkaline* materials, although albumen may be present, it will *not* coagulate by heat. Nitric acid, however, by removing the alkalinity, will induce coagulation. Some curious results have been made out by Rayer and Guibourt<sup>c</sup> on albumen. They have shown, that nitric acid in *minute*, acetic acid in *large*, and phosphoric acid in small or large proportions, will *deprive* albumen of the property of coagulating by heat. But—what is remarkable—larger quantities of nitric acid will immediately precipitate it. These are practical facts, that should be known, in the examination of the urine. It may here be stated,—on the authority of recent microscopic discoveries and researches by Quevenne, Donnè, and others,—that the epithelium of the genito-urinary mucous surface, undergoes continual desquamation, and that in some diseased states this desquamation increases very much; so that, unless carefully examined, the turbidity of the urine dependent upon their presence may be mistaken for albuminous opacity.—*Thomas Williams.*]

*Bright's Discoveries.*—We are indebted to Dr. Bright for a knowledge of the fact, that, in organic disease of the kidney, the urine is generally in this albuminous state. Andral, in his "Clinical Reports," had previously mentioned a case where he found the urine albuminous, and the kidney in a granulated state; but as he

<sup>a</sup> "Library of Medicine;" Volume 5; Pages 117 to 121.

<sup>b</sup> Dr. Christison, on Granular Degeneration of the Kidney; Page 44.

<sup>c</sup> "Traité des Maladies des Reins, et des Alterations de la Sécrétion Urinaire." Par M. P. Rayer, Tome Premier; Page 625.

had no more facts in his possession, he came to no general conclusion; nor would he have been justified in doing so. Dr. Bright, however, has collected a large number of cases; and he finds, that when the kidney is in a disorganized state, the urine is generally albuminous.

*Organic Disease not necessarily present.*—When the urine is albuminous, it does not follow that the kidney *must* be in a state of organic disease. But still, even in Andral's case, the kidney was *affected*, and stated to be gorged with blood. Some have gone farther than this; and declared that nobody can have albuminous urine, without organic disease of the kidney. I cannot subscribe to this assertion; for I have seen patients who were perfectly well a day or two before, but who have been exposed to cold and wet; symptoms of inflammatory dropsy have come on; the urine has become albuminous; but, on bleeding them, the dropsy has presently been got the better of, and the urine has recovered its healthy appearance. Why these poor people should be supposed to have had diseased kidneys, merely because they had albuminous urine for a week, is not easily understood. I could not open them, to ascertain whether their kidneys were diseased; but as they are in perfect health now, and had been in perfect health just before, and the urine is no longer albuminous, I do not believe there is any more foundation for supposing the existence of organic disease, than there is for supposing that cancer of the stomach is present in every case of temporary dyspepsia; because, when people *die* of dyspepsia, we find more or less organic disease. Although a person may *die* with albuminous urine, and we find structural disease of the kidney, it does not follow that, when the urine *temporarily* presents the same phenomenon, and the person recovers, he has had any thing more than a functional complaint. Because the affection of the kidneys may arrive at such a degree of intensity as to destroy life, and organic disease is then always found, it does not follow that the *temporary* formation of albumen in the urine, should be any thing more than a functional disturbance of the kidneys. I should draw just the opposite conclusion; and should suppose, that if the symptoms were temporary, the disease must be functional. Dr. Mackintosh informed me, that some medical students in Edinburgh ascertained, that when they ate pie-crust, and it produced dyspepsia, their urine became albuminous. They frequently repeated this experiment, and the circumstance is nothing more than I should expect. Dr. Graves has done much to dissolve the supposed invariable connection between albuminous urine and disease of the kidney. He shows that it often depends on disease of the *liver*.<sup>a</sup>

If, however, no organic disease whatever can be discovered, in any of the other viscera of the body, and there are no indications of acute febrile action;—if the patient be evidently sinking under dropsy, and the urine is albuminous, I believe, in the majority of cases, (provided the urine is *constantly* albuminous,) that there is organic disease of the kidney. It is generally found granulated, mottled, or laboured under great sanguineous congestion.

*Specific Gravity.*—[We ascertain, in the next place, the density of the suspected urine. The same discrepancy is to be regretted in the statements of different authors respecting the average specific gravity, as respecting the average quantity, of healthy urine. While Dr. Prout places it anywhere between 1010 and 1015 (that of distilled water being 1000), M. Solon describes it as ranging from 1020 to 1024, and Dr. Christison estimates it at 1024 or 1025. We shall assume the latter to be the nearest to the truth;—both because it is avowedly founded upon the result of numerous trials; and because, if it be not exact, it is less likely than the number given by Dr. Prout, to lead us into erroneous conclusions in reference to the disease in question.

Perhaps it is scarcely requisite to admonish the reader, that the question of specific gravity must always be contemplated in relation to the absolute quantity of urine secreted. The specific gravity depends upon the proportion of the solid constituents of the urine contained in a given quantity; if the aqueous portion be

<sup>a</sup> See his valuable papers in the "Dublin Journal of Medical Science."

augmented, the effect upon the absolute density will be the same as if the solid contents were proportionally diminished. But when, as frequently happens in this renal disease, the specific gravity decreases while the quantity of urine decreases also, that conjunction of phenomena becomes especially significant.

The three circumstances that have now been mentioned (all of which it is easy to determine)—namely, the quantity of urine secreted in a given time, its impregnation with albumen, and its specific gravity—constitute, together and by comparison with each other, a very accurate and trustworthy test of the presence or absence of the renal disease.

The albumen, not unfrequently, disappears for a time, even early in the disease. Sometimes it ceases altogether, although the renal disease may be fixed. This is most frequently the case in the advanced stages of the disease. The general rule is, that the albumen is plentiful and almost constant in the outset of the malady; less certainly present as it proceeds; and sometimes entirely absent in its latter periods. Now it is of importance to remark, that the alteration in the specific gravity of the urine follows a contrary law. The declension of density, so far from being corrected, augments with the progress of the disorder. Hence the one of these morbid phenomena is a valuable check upon the other;—considered as an index of what is going on in the kidney.

At first the specific gravity is not much below the natural standard; but it sinks from 1020 perhaps to 1016; and at length, as the renal malady increases, to 1010, 1008, and even lower. Solon once noticed it as low as 1003, when the diurnal quantity was forty-four ounces. The lowest density ever noted by Dr. Christison,—the quantity not being in excess,—was 1004. We may, with Solon, place the average specific gravity of the urine in this complaint at 1013.

Allowing always for the quantity of the secretion, if we find that albumen ceases to manifest itself on the application of the proper tests, and the density be decidedly low, we must not be led to infer or hope, merely from the absence of albumen, that the kidneys are sound.

These characters of the urine, rightly weighed and interpreted, reveal therefore not only the existence of the renal disease, but also, with great probability, the stage or degree it has reached.

### *d. Changes in the Blood in Renal Dropsy.*

It has also been ascertained, in the disease we are now considering,—1. That the blood often contains urea. 2. That the serum of the blood is apt to be of a lower specific gravity, and to be less albuminous, than in the healthy state. 3. That the proportion of its fibrin varies. 4. That the colouring matter of the blood gradually decreases in quantity during the progress of the disease.

*Urea in the Blood.*—Modern physiologists are agreed, that urea is not formed by the kidneys; but merely abstracted by those organs from the blood, as fast as it is received or generated there. Whenever this process of separation is suspended or defective, a portion of urea remains in the circulating blood, and may be detected by its proper tests. Urea has been thus discovered in the blood of animals after the extirpation of their kidneys. In the blood of patients afflicted with renal dropsy, it has been found as plentiful even as in their urine; and not in the blood only, but in the various fluids derived from the blood; and particularly in the liquids effused into the ventricles of the brain, the pericardium, pleuræ, and peritonæum. According to Dr. Christison, whenever there is a material reduction of the daily discharge of urea by the urine, it may be distinctly found in the blood; but not otherwise. And he considers the reduction to be material, if the quantity excreted be diminished to about one-third of the natural amount.

*Deficiency of Albumen.*—Again: the serum of the blood has been ascertained to contain, in this disorder, a less than common share of albumen, and to be of an unnaturally low density. The average specific gravity of healthy serum is 1030. It is apt to be reduced to 1024, 1020, and even to 1013. Dr. Babington declares

that, in cases of coagulable urine, he has always found the specific gravity of the serum much below the healthy standard. The quantity of albumen in healthy blood averages from 65 to 69 parts in 1000. In this disease, Dr. Babington has met with as little as 16·10 parts. The general truth of these statements is corroborated by the results of Dr. Christison's experience; but the information which he renders is more precise. He has noticed that a definite but inverse relation subsists between the coagulability of the urine and the density of the serum;—that the more albumen there is in the former, the lower is the specific gravity of the latter fluid. Hence it is, that the density of the serum is most diminished in the earlier periods of renal dropsy; inasmuch as the urine is then most highly charged with albumen. In proportion as albumen, with the progress of the malady, becomes less perceptible in the urine, it becomes more abundant in the serum; the specific gravity of which returns towards, and may reach, the degree that belongs to health. But in all stages of the disease, whenever albumen appears plentifully in the urine,—as during febrile reaction,—the density of the serum sinks.

*Increase or Decrease of Fibrin.*—Again; it results from the concurring experience of Dr. Christison and Dr. Babington, that the ratio of the fibrin in the blood is usually increased in the early stage, and during the existence of febrile disturbance in any stage of the disease. At the same periods, the blood presents the buffy coat. In ordinary circumstances, after the early stage has gone by, the quantity of fibrin most commonly reverts to the natural proportion. In healthy human blood, Dr. Christison has found the quantity of dry fibrin to vary from 25 to 52 parts in 10,000. During the early stage of the renal malady, he has known it as high as 82, and as low as 30 parts. Reaction being present, he has met with as much as 85 parts in the middle stage, and 56 parts in the advanced stage. In other circumstances, it commonly ranges between 27 and 43 parts.

*Decrease of Hæmosine.*—Lastly: the colouring matter of the blood, which is but little if at all affected in the outset, diminishes gradually where the disease continues; and at length is so much reduced, as to form less than a third of the healthy average. If venesection be occasionally employed, this process of depravation is accelerated; but it takes place, whether blood be artificially withdrawn from the system or not. "I am acquainted," says Dr. Christison, "with no natural disease,—at least of a chronic nature,—which so closely approaches hæmorrhage, in its power of impoverishing the red particles of the blood." In the male sex, the healthy proportion of the hæmosine is 1335 parts in 10,000. In a young man, ill three months and a half, subsequently to scarlatina,—who had never been bled before,—Dr. Christison has seen this reduced to 427. This change in the blood is invariable.

#### *e. Complications of Renal Dropsy.*

*With Cerebral Derangement.*—One of the most common and most important of these complications, is the occurrence of what are compendiously called "head-symptoms;"—various manifestations of derangement in the cerebral functions;—headache,—drowsiness,—delirium,—epileptic seizures,—or apoplexy. So frequently, indeed, is the death of the patient preceded by convulsions or coma, that Dr. Christison has rightly considered this to be the "natural termination" of the disease, or "the mode in which it proves fatal, when life is not cut short by some other incidental or secondary affection." Of seventy fatal cases observed by Dr. Bright, death was ushered in by well-marked cerebral symptoms in thirty.

The circumstances in which these affections of the brain take place, have been ascertained with tolerable accuracy. They are almost always preceded by a great diminution, or an entire suspension, of the secretion of urine. This connection of coma with suppression of urine, has long been recognised; and it is well exemplified in the disease under consideration. If the quantity of urine becomes very scanty,—so as to amount to no more than two or three ounces in the twenty-four hours; and especially if the deficiency occurs suddenly; and more particularly if there be a

total cessation of the secreting function, we may reckon upon the speedy dissolution of our patient, and that he will die comatose, and perhaps after convulsions. But this rule is not so strict as to offer no exceptions. Occasionally (though seldom) it happens, that the urine is reduced to a very small amount, while the head remains unaffected. Of this Dr. Christison records a remarkable instance:—One of his patients passed no more than two ounces of light urine daily, for nine days before his death; yet he remained sensible to the very last minute of his existence, and died simply of inanition. Somewhat less unfrequently, apoplectic symptoms arise and carry off the patient; although there has been no extreme or material reduction in the quantity of urine.

When a case has terminated in this manner, serum is sometimes found accumulated in unnatural measure in the cerebral ventricles, and in the tissue of the pia mater. The dropsy has extended to the brain; and, in these circumstances, although it may be difficult or impossible to determine when and with what rapidity the serum has been effused, its presence and its pressure may fairly be assumed to have produced the fatal symptoms.

In many instances, however, there is found no morbid collection of water within the skull, nor any appreciable change; and in some instances there is no dropsy of any part: and this fact—taken together with the usual failure in the quantity of urine, and the ascertained presence, sometimes, of urea in the blood, and even in the natural serosity of the encephalon—has led to the construction of a theory, which refers the ultimate symptoms (the stupor and the death), to the poisonous influence of the urea of the unpurified blood upon the brain and nervous system. Another not improbable hypothesis connects the supervention of stupor and coma with a pale and watery condition of the blood. That similar symptoms are apt to arise in conjunction with a similar defect of hæmatosine, has been well known since the publication of the remarks of the late Dr. Gooch, and of Dr. Marshall Hall, on that peculiar form of cerebral affection. It would seem that, in such cases, the functions of the brain are exercised irregularly, languidly, and at length not at all;—in consequence of the failing supply of its appropriate stimulus through the arteries.

*Inflammatory and other Affections.*—Another striking circumstance observable in this disease, is a readiness of various organs of the body, and particularly of the serous membranes, to inflame. Such intercurrent acute inflammation is a not uncommon cause of death. The pleura is much more often affected in this manner, than the peritonæum or the pericardium.

Disorder of the stomach and bowels is, certainly, a frequent companion of the malady;—nausea,—vomiting,—flatulent distension,—diarrhœa.

It would appear, however, that these incidental complications prevail with irregular frequency in different places. They are probably owing, in some measure, to local and peculiar agencies. Thus, vomiting and diarrhœa have been more familiar to the Edinburgh observers, than in London to Dr. Bright, or in Paris to M. Solon; while the headaches and coma so often witnessed by the British physicians, have been comparatively uncommon in France.

*With Cardiac Disease.*—All the writers on this subject, acknowledge the frequent association of cardiac disease with the renal; and, with respect to this concurrence of structural alteration in the heart and in the kidney, several obvious and interesting, but hitherto unsettled, points of inquiry present themselves. Some of these we may mention,—as being fit subjects for future investigation. It is generally difficult, when we find both organs altered in structure, to trace the course of the patient's maladies so accurately, as to determine which change has been primary, and which consecutive. It is highly probable, indeed, that, in certain cases, the cardiac disease and the renal disease have no relation to each other, as cause and effect; but are both consequences of some general cause;—of habitual intemperance, for example.

*Is the Renal Disease ever produced by the Cardiac?*—We might more easily arrive at an answer to this question, if the real nature of the change which the kid-

ney undergones were better understood. In the acute renal cases, where they prove early fatal, the kidney is always found to be gorged with blood; and the accustomed admixture of blood with the urine warrants the belief, that the same condition was present in patients who have recovered. From this state of engorgement (which is not acute inflammation, since the ordinary events of acute inflammation in that organ do not follow) springs, apparently, the subsequent series of changes. It is therefore a plausible conjecture, that whatever tends to cause congestion of the kidney, tends also to aggravate, and may even produce, the peculiar changes in question. That disease of the heart, and especially such disease of the heart as leads to dropsy, occasions congestion of the venous system, and in this way gorges the viscera with blood, is well known. Under this influence the liver often enlarges. So that, in cardiac disease connected with dropsical accumulation, we might *a priori* expect congestion of the kidney, and structural alteration in consequence of such congestion.

A serious objection to this view of the matter is presented by the fact, that dropsy often arises from disease of the heart, lasts long, and ultimately proves fatal, without the occurrence of albuminous urine, and without any appreciable change of structure in the kidney. It is plain, also, that passive congestion of the kidney, produced by disease of the heart, cannot be the sole cause of the renal change; for that change is sometimes well marked, though the heart has been unaffected.

*Does the Renal Disease ever produce the Cardiac?*—That it may do so is, at least, very conceivable. The heart, no less than other parts of the body, will suffer from the deterioration that has been shown to take place in the blood in these cases. A sort of anæmia is produced; and anæmia implies debility of the muscular texture of the heart, and tends to dilatation of its cavities; and the weak heart, becoming irritable also, grows thicker as it labours. This is the form of cardiac disease which has been found, in many cases, to be coincident with renal dropsy.

Where the heart, as well as the kidney, has undergone organic change, the disposition to dropsical accumulation will evidently be augmented; but what share these two organs respectively possess in producing the dropsy, it is very difficult, and practically not very important, to determine.

*Pain of the Loins.*—Pain or tenderness of the loins is sometimes an accompaniment of the renal disease; this symptom is more often present in the early than in the latter stages of the malady. It occurred in one-third of the twenty-eight cases narrated by M. Solon. Dr. Gregory noticed it in the half of his patients.

*Vesical Irritability.*—Irritability of the bladder, or rather a morbid frequency of the call to micturition, has been spoken of by Dr. Bright and Dr. Christison as a common symptom in renal dropsy. It is a symptom, however, belonging to so many other disorders that, taken by itself, it has but little value.

*Causes.*—The causes of this disease are obscure. It is clearly ascertained that its most obvious symptoms, in their chronic form, have, in very many instances, begun soon after the exposure of the body to wet and cold under unfavourable circumstances. But it is by no means certain—indeed, the probabilities preponderate on the other side—that, in these instances, the renal disease had not previously existed in its latent state. The influence of external agencies upon the excreting functions of the skin, in exciting definite symptoms, is beyond question.

It is certain, also, that what is called “acute dropsy” (already described<sup>4</sup>) arises in similar circumstances of exposure, and is attended with a marked disturbance of the functions of the kidneys; and chronic renal dropsy has sometimes been noticed as occurring in persons who had previously suffered, and had apparently recovered, from the acuter form. Are we not warranted in supposing that the recovery was imperfect in such cases?—that the kidney had sustained irretrievable injury?—and that the disease, although (under treatment, or by lapse of time) it had become tranquil or latent, was ready again to give indications of its existence, upon any repetition of its exciting cause?

<sup>4</sup> See Pages 154 to 156.

The possible dependence, in some cases, of the renal disease upon disease of the heart, has been already noticed.<sup>a</sup>

Again: it is matter of common observation, that intemperate habits have often preceded the development of the disease. Yet we conclude, that intemperance is rather a *predisposing* than an *essential* cause;—from the fact that the complaint is not unknown among children, and other persons whose manner of life has been strictly temperate. A marked example occurred lately to the writer in a young girl, fifteen years of age, who had not menstruated. And this leads to another remark; namely, that dropsy with albuminous urine has been observed not unfrequently to follow a sudden check or suppression of the catamenia. In a few instances, it has seemed to owe its origin to blows received upon the loins, or to extreme fatigue.

*Age at which it occurs.*—The disease occurs at all ages; less often, however, in extreme youth, than afterwards. This malady is much more common in adults;—not, in all probability, because the system is more readily affected by it at one period of life than another; but because, as life advances, the circumstances which tend to produce or foster it become of more frequent operation;—namely, intemperance, exposure to vicissitudes of temperature, fatigue, and disease of the heart. It occurs, probably for the same reason, oftener in men than in women.<sup>b</sup>

#### SECTION IV.—CARDIAC DROPSY.

[The mode in which disease of the heart may occasion general dropsy, has already been sufficiently explained.<sup>c</sup> In such cases, indications (more or less distinct and certain) of the cardiac affection, are generally observable. We judge that the dropsy has this origin by the following circumstances:—1. The presence of thoracic symptoms; such as cough and dyspnœa, occurring prior to the dropsy. 2. The direct signs of cardiac disease, such as distended jugular veins, irregular movements of the heart, unnatural impulse, or altered sounds. 3. The history of some previous acute disease, affecting especially the left side of the thorax; or, particularly, by an account of antecedent arthritic rheumatism. 4. The advanced age of the patient;—rendering it probable that some of those organic changes in the heart and large blood-vessels are in progress, which are almost natural in the decline of life. 5. The absence of all evidence of renal disease. But we see many persons who labour unequivocally under organic disease of the heart, yet who survive even for years without becoming dropsical. The interesting question, therefore, at once arises,—“Of what kind of heart-diseases is dropsy a consequence and symptom?” The answer is,—“Of such disease of the heart, as produces a certain amount of permanent obstruction to the passage of the venous blood.” The permanent obstacle must be sufficient, in degree, to distend the veins beyond their natural capacity. Hence dropsy is especially associated with dilatation of the right chambers of the heart. It would be incorrect to say, that the dropsy is dependent on such dilatation; for the dilatation itself is at once an effect and a sign of impeded transmission of the blood from the right side of the organ. Nor is such dilatation a necessary attendant on the general accumulation of water. The impediment may be sufficient to gorge the right cavities; while it is yet too slight in amount, or too recent in duration to have dilated them.

*Conditions on which it Depends.*—What, then, are the conditions which imply an impediment of the kind we are now considering? The two great vital organs contained within the thorax,—namely, the heart and the lungs, form different parts of one common mechanism; the object of which is to supply every part of the body with blood that has been recently exposed to the air; and these organs, thus closely related in respect to function, are, moreover, so reciprocally dependent, that any

<sup>a</sup> See Page 164.

<sup>c</sup> See Page 151 and 152.

<sup>b</sup> “Library of Medicine;” Volume 5; Pages 123 to 130.

structural change occurring in the one tends to produce disease, sooner or later, in the other also.

It is well worthy of observation, that the order in which the diseases of these organs are connected, as cause and effect, is a definite and constant order;—taking place in the direction opposite to that in which the blood circulates. Disease existing in any part of the circuit formed by the right chambers of the heart, the lungs, and the left chambers, becomes a cause of consecutive disease, first in the part immediately behind it. The heart itself, as is well known, is seldom diseased throughout, or diseased in a like manner and degree throughout; and its partial affections, which are exceedingly common, obey the law just announced, as being applicable to the whole circuit of the lesser circulation. Thus, organic disease situated at the aortic outlet of the heart, and of such a kind as to hinder the exit of the blood from the left ventricle, gives rise to permanent changes in that ventricle;—to hypertrophy, either with or (less commonly) without dilatation. The hypertrophy is here a truly compensating and conservative change; and when it is exactly proportioned to, and keeps pace with, the impediment which has given it birth,—so as precisely to countervail and balance that impediment, no delay takes place in the stream of arterial blood; and the injury is, as yet, confined to the left ventricle. That chamber is remodelled and adapted to its purpose by the *vis medicatrix naturæ*; and no other evil manifests itself than, perhaps, some slight encroachment and pressure upon the neighbouring parts,—in consequence of the augmented volume of the heart.

So long as the mitral valve remains healthy and effective, it offers a barrier or protection against the extension of the disease in the direction which is retrograde in relation to the course of the blood. But at length, in most instances, the stress becomes sensible further back. The left auricle and the pulmonary veins become embarrassed, distended, dilated; and the blood is detained in the lungs. Then dyspnœa commences. At first it is occasional only;—whenever the heart is tasked with the conveyance of a greater quantity of blood, in a given time, than usual; as in brisk movements of the body, or strong emotions of the mind; or when it is oppressed by circumstances that diminish the capacity of the chest;—by a full meal, therefore; by flatulent distension of the stomach and intestines; or by the recumbent posture. Afterwards the dyspnœa becomes more or less constant and distressing.

This gorged and embarrassed condition of the lungs, even when it is permanent, and has reached a considerable degree, may exist without materially interfering with the functions of the right cavities of the heart; for the pulmonary plethora may be relieved by increased secretion from the bronchial mucous membrane. Dyspnœa, even when it has thus become habitual, may precede for some time any appearance of dropsy.

At last, however,—the effects of the original evil augmenting and extending,—the right ventricle also becomes unable duly to propel its contents into the pulmonary vessels. It continues morbidly full; is first distended occasionally, then permanently, and at length dilated; and with the dilatation we have a turgid venous system;—of which we see a part in the prominent veins of the neck.

In this manner, then, may be explained the series of symptoms, so commonly noticed as life advances. We find irregularity of the pulse, preternatural impulse of the heart, occasional dyspnœa, larger crepitation (habitually audible in the lower portions of the lungs), and more or less expectoration (sometimes tinged, sometimes even loaded with blood). Eventually the ankles begin to swell, and the patient becomes by degrees (unless cut off earlier in some other way) decidedly and universally dropsical.

*Signs accompanying Cardiac Dropsy.*—Many of the direct signs of diseased heart may exist, therefore, while there is no dropsy;—intermissions and irregularity in its movements, palpitation, or the impulse proper to hypertrophy. But when dropsy has supervened, we may expect also the signs which denote the dilatation of the right chambers. The heart is hard and felt to beat beyond the præcordial limits;

the pulsations become feeble and unequal, if they were not so before; the patient is liable to fluttering palpitations,—to extreme and panting dyspnoea on the slightest exertion;—even on taking food into the stomach, or adopting the horizontal posture. His skin assumes a dusky hue; and his lips and extremities are apt to be livid. In these cases, the anasarca first becomes manifest about the ankles. During the earlier stages, the œdema disappears in the night, and returns towards evening. It is sometimes confined, for a considerable period, to the legs; but by degrees it ascends towards the trunk of the body,—the integuments of which become doughy; the scrotum fills, and water collects in the serous bags of the abdomen and thorax. In extreme cases, the dropsy is universal,—pervading the cellular tissue of the head and face and upper extremities. As the accumulation of serous fluid is commonly gradual, the reticular tissue,—partly perhaps through maceration, but chiefly from continued pressure and stretching,—loses its elasticity; and the œdema is soft, and pits readily. Sometimes, the fluid continuing to increase, the cuticle is separated by it; and large vesications take place on the limbs; or some part of the cellular tissue sloughs, and a breach of surface is made. The fluid drains off, by this vent, in great abundance;—to the signal relief of the patient. This beneficial accident furnishes a valuable hint to the practical physician.

*Causes; Age.*—The most common of them all is advancing life. The morbid change appears to commence in the aorta; and consists in a deposit of cartilaginous or calcareous matter beneath its innermost membrane. By this alteration, the elasticity of the artery is impaired; it acquires a facility of dilatation; and the onward passage of the blood, after it issues from the left ventricle, is virtually delayed: hence increased efforts, on the part of that hollow muscle, to propel its contents; and the gradual backward propagation of organic change. It would perhaps be more correct to attribute those alterations of structure to that decay, which occurs in virtue of a law that extends to all organized bodies, rather than to disease. Earthy concretions in the coats of the arteries are met with (according to Bichat's experience) in seven persons out of every ten who die beyond the age of sixty; and Dr. Baillie declares ossification to be much more common in old persons, than a healthy state of the arteries.

*Inflammation of the Cardiac Membranes.*—But the cardiac mischief often originates, at an earlier period of life, in acute or chronic inflammation of the membranes that invest and line the heart. Chronic endocarditis, marked at its outset by slight or vague symptoms, appears to be of common occurrence; for its effects are very frequently seen in the dead body. Among the causes of this chronic disease, habitual intemperance,—especially in excessive or long-continued indulgence in ardent spirits,—holds, we believe, the first rank; but acute inflammation of the pericardium, or of the endocardium, or of both simultaneously, is also a frequent source of subsequent changes in the proportions of the several chambers of the heart. Such inflammation may arise from ordinary causes; and exist and run its course independently of any other diseased condition. In by far the majority of instances, however, it takes place in connection with acute articular rheumatism. The frequency of this complication, in those persons at least who suffer from rheumatism in London, is very remarkable. The heart is found to be more or less involved in the disease, in not less than one-third of all the patients admitted into our hospitals with acute rheumatism. Of *rheumatic carditis* the following particulars have been noticed:—1. Its proper symptoms are often unheeded by the patient, amid the severer pains that affect his limbs; and may easily be overlooked by the practitioner who does not vigilantly search for them. 2. When the cardiac symptoms are well marked, or (being but slightly marked) have been looked for and detected, they generally cease (in a great measure, or entirely) with the cessation of the joint-disease they accompany; or those signs which remain (as unnatural sounds) are not of a kind to induce evident distress, or to claim the attention of the patient. 3. Nevertheless the organ seldom (according to the writer's belief, never) reverts to its former state, or undergoes complete repair; but the structural changes

left by the inflammation form the germ of further changes; progressive in their character, and ultimately destructive of life.

Rheumatic endocarditis is more common than rheumatic pericarditis. Each tends gradually to produce such conditions of the heart as occasion dropsy; and it may be worth while, in our endeavour to analyze and trace home these conditions, to consider for a moment the manner in which the consecutive changes are brought about.

*Disease of the Valves.*—When, in the course of rheumatic fever, inflammation befalls the lining membrane of the heart, it affects chiefly the valves; especially, but not exclusively, the valves of the left side of the heart; and, most constantly of all, the sigmoid valves of the aorta. It will at once be seen how these valves,—by being thickened, or shrivelled, puckered, or rendered stiff by adhesion to neighbouring parts, or affected with ulceration, or perforation, may have their peculiar functions permanently injured;—so that they are apt to become, on the one hand, an obstacle to the free passage onwards of the blood;—or incapable, on the other, of effectually preventing its backward passage. Hence an imperfect emptying of the chamber that precedes the seat of the special alteration;—hence continued striving and hypertrophy; and ultimately, according to the degree and place of these changes, an extension of disease towards the right side of the heart.

Again: when acute pericarditis is set up, the inflamed membrane either adheres—partially it may be, but more often at all points—to the heart; or it does not adhere. If it does not, the patient dies in the primary attack. If it does, all signs of cardiac disease may disappear. But the seed of future mischief has been sown: "*hæret lateri lethalis arundo.*"<sup>a</sup> The free movements of the heart are fettered by the adhering bag; the muscle is urged to stronger or more frequent contractions; and this is aided by the effects of the endocarditis; which probably never fails to accompany, in some degree, the inflammation of the outer membrane. Hence, again, the extension of disease in the direction contrary to that of the blood.

When these facts are taken into account, they will serve to explain how it is, that when we come to examine a patient labouring under manifest disease of the heart, we so very often trace, in his history, one or more attacks of acute rheumatism. They who have not been in the habit of putting the question as to this point, would be surprised at the number of such cases. When the articular rheumatism was present, the heart-affection was perhaps unnoticed; or, if noticed, the patient (as he and his medical attendant are apt to think) got quite well; and when, at length, unequivocal symptoms of organic disease of the heart force themselves upon our attention, its rheumatic origin is too often unsuspected or forgotten.

Obstruction to the venous current and dilatation of the right chambers of the heart may be propagated, in the manner now described, from the left side of that organ. But the obstacle may begin at an earlier link of the chain;—as in the lungs; and an incidental question of much interest also presents itself; namely:—"In what kinds of pulmonary disease is cardiac dropsy liable to originate?"

*Pneumonia.*—Whatever tends to gorge the right cavities of the heart with blood, tends also to the production of general dropsy. On this principle it might be expected, that dropsy would form a symptom or direct consequence of some of the acute disorders of the organs of respiration. When, in pneumonia, a large portion of one or both lungs becomes impervious by air and blood, or when pleurisy fills one side of the thorax with liquid,—which, by its pressure, shuts out at once air and blood from one half the respiratory apparatus,—the egress of the blood from the right ventricle, and therefore from the venous system, must be impeded. And, in truth, dropsical effusion is occasionally the result of such disease. That it does not occur more frequently, is to be attributed to the free evacuations, and the abstinence, which are early put in force in these complaints; and which relieve the distension before it produces effusion. In one remarkable instance of acute laryngitis, which fell under our care, the whole body was anasarcaous at the time of the patient's

<sup>a</sup> "The deadly arrow remains fixed in the side."

admission into the hospital. His life was saved by tracheotomy; but the dropsical effusion had previously disappeared, a few hours after one copious bleeding from the arm. This case illustrates the tendency to dropsy arising under impeded transmission of blood through the lungs; it both exhibits a conformity to the general principle, and affords a probable explanation of its infrequent operation.

*Tubercular Disease.*—Again: lungs that are hollowed out into large cavities, or rendered solid over a wide space by numerous tubercles, are manifestly incapable of admitting into their vessels, from the right side of the heart, the ordinary quantity of venous blood. In these cases, however, the whole mass of blood is diminished, and kept within the limit which does not imply distension of the veins, by the constant agency of various causes;—by the imperfect nutrition of such patients, in consequence of abdominal disease; by the sometimes copious expectoration; by the wasting diarrhœa; and by the profuse perspirations. Accordingly, dropsy is an unusual symptom in pulmonary phthisis, or shows itself in the latter periods only of the disease, in the form of œdema of the legs; and its occurrence then is mainly owing to the debility which affects, in common with the other muscular parts of the body, the moving organ of the blood.

*Emphysema of the Lungs.*—The disease of the lung which most commonly and certainly, though often very slowly, leads to dropsy, is dilatation, with or without rupture, of its air-cells;—in modern nomenclature, "*emphysema of the lungs.*" In this morbid condition, many of the smaller blood-vessels of the organ become gradually obliterated;—in consequence of the pressure arising from the stretching of the membranes, upon or between which they ramify. When the dilatation is extensive and advanced, the pulmonary texture is visibly white and bloodless. Meanwhile, the nutrition of the body is not impaired. The same quantity of blood continues to be returned towards the heart; but it finds not a ready entrance, when sent from that organ, into the pulmonary blood-vessels. A certain amount of accumulation in the right side of the heart and great veins becomes habitual; at length, the capillary vessels feel the congestion; and more or less anasarca takes place.

*Debility of the Heart.*—The same effects upon the venous circulation may arise, when there is no primary organic disease of the heart, from mere debility of its muscular tissue;—such as often occurs in anæmia;—in what is vaguely called "*cachexia*;"—in exhaustion from habitual loss of blood;—in any case, in short, in which the muscular tone is considerably reduced. The muscle is ill-nourished by the thin and watery blood; it cannot tighten upon its contents with sufficient force to drive them effectually forwards; it may even dilate somewhat under the centrifugal pressure of the resisting liquid; the attenuation of the blood concurs to facilitate transudation of its serosity through the coats of the minute vessels; and dropsy ensues. The anasarca thus arising from debility of the heart and poverty of blood in young, feeble, or delicate women, is so common, as to require a more particular description of its features and circumstances. It seldom goes beyond œdema of the legs; but occasionally the trunk and arms are slightly infiltrated, and the face is puffy and bloated. It is rarely that the large serous cavities are affected.

These patients are pale; their lips, gums, and tongue are without colour, or but faintly red; their muscles flabby and weak. They are "nervous," easily agitated, of variable spirits, and often hysterical;—subject to palpitation of the heart and shortness of breath whenever they ascend a hill, or a flight of stairs, or make any exertion. In very many of them, the systole of the heart is attended with a bellows sound; and a roaring noise, continuous or intermittent,—like the murmur heard in certain shells when applied to the ear,—may be heard in the vessels of their neck. Their extremities are readily chilled; their feet are cold at night; and they suffer in the winter from chilblains. They complain of pain in one or the other hypochondrium, most often in the left; and of headache, which either occupies now one and now the other temple, or is more generally diffused.

In most instances they are subject to amenorrhœa, or irregular menstruation.

Commonly, the discharge is scanty, pale, postponed, and attended with pain; and leucorrhœa is present in the intervals. Sometimes they have tenderness along the course of the veins of the lower extremities;—particularly of the saphena and femoral veins. This symptom is frequently observable when the irregularity dates from some sudden check to the actual process of menstruation. Usually the appetite of these patients is slender and fastidious; and they do not like meat.

This form of cardiac dropsy is almost always curable. Most of the symptoms are referable to a deficiency of red blood; and gradually disappear, as the improving complexion indicates that the quality of the blood is restored.

It is necessary to remark, that tumours of various kinds (aneurisms of the aorta, cancerous growths, &c.)—occupying the thorax, and causing pressure upon the large veins in their neighbourhood—may be the cause of general dropsy. The same is true of certain malformations of the chest, and of certain displacements of the parts within it. In all such cases, the production of the dropsical accumulation may be accounted for upon the same general principles as have been applied to the explanation of cardiac dropsy.<sup>a</sup>

## SECTION V.—GENERAL TREATMENT OF DROPSY.

[We have next to consider the principles by which our practice in the *treatment* of dropsies is to be regulated. As, in most cases of dropsy, there are two distinct sets of symptoms observable,—namely, those which result from the presence of the accumulated water, and those which depend on the bodily conditions that have produced the accumulation,—so there will arise, in most cases of dropsy, two main indications of treatment;—the removal of the dropsy itself, and the suspension of its physical cause. The latter object implies either the complete remedy of the morbid conditions productive of the dropsy, or the establishment of some new condition which shall prevent or counteract their operation.

These two main indications may be fulfilled, in different cases, with very different degrees of facility. If the morbid conditions productive of the dropsy be cured, or their tendencies averted, the accumulated liquid will in most cases soon disappear of itself. But even in these favourable circumstances, its departure may often be accelerated by art. On the other hand, the removal of the accumulated water may often be accomplished; while the more important indication,—which strikes at the root of the disorder, and would prevent its return,—is capable of being effected only slowly, and with difficulty,—imperfectly, or not at all.

The evacuation of the dropsical fluid is first to be attempted through the medium of the blood-vessels. Whatever empties the turgid veins, enables and disposes them to refill themselves, by drinking up the superfluous liquids of the body;—to be afterwards discharged by some of the natural channels of excretion.<sup>b</sup>

*Inflammatory Dropsy.*—All these particular dropsies closely resemble hæmorrhage and fluxes. It is to be remembered, that hæmorrhage and fluxes are frequently of an active inflammatory kind; and are to be treated, not by remedies calculated to arrest the flow of fluid, but by the remedies of inflammation;—not by astringents, but by antiphlogistic measures. On the same principle inflammatory dropsy is to be treated, not by remedies calculated to carry off the fluid, or stop up the mouths of the vessels which pour forth the secretion, but by remedies calculated to remove inflammation. Dr. Blackall, indeed, says that “a correct guide to venesection may be found in the firmness, copiousness, and early appearance of an albuminous coagulum in the urine; its *limits*, in the improvement of the discharge of albumen in the urine (that is to say, in the diminution of the coagulum), in the state of the blood, and the relief of the other symptoms.” But I am satisfied, that if we take the state of the urine as our guide, we shall often practise very badly.

<sup>a</sup> “Library of Medicine;” Volume 5; Pages 111 to 116.

<sup>b</sup> “Library of Medicine;” Volume 5; Page 109.

I have found it very common for persons to be cured of dropsy by bleeding, although no albumen could be discovered in the urine; while, on the other hand, during the presence of albumen in the urine, persons have derived little benefit from bleeding. I have also seen abundance of albumen in the urine, with such debility of the frame, as to forbid bleeding altogether. I should therefore advise that, in every case of dropsy, the question as to bleeding, should be determined simply by observing whether there are inflammatory symptoms or not;—considering, not the state of the urine, but whether the symptoms are those of inflammation or not. If in any case of dropsy, we find a full, strong, and quick pulse, with strength of body, we are then to presume that the case is of an inflammatory nature. If there be local pain, and other symptoms of local inflammation anywhere,—whether in the head, chest, or abdomen,—that is quite sufficient to determine the inflammatory nature of the case. Again: if we cannot learn much from these particulars,—if the pulse do not show any phlogistic diathesis; and if the head, chest, and abdomen, be particularly free from inflammation, and the disease have come on suddenly,—as inflammation often does;—if it be not the work of slow disease, like visceral affection; but has come on suddenly, and come on from the common cause of inflammation (such as the application of cold and wet, especially when the body is over-heated);—then the presumption is that the case is inflammatory; and we shall not do wrong if we bleed, so far as the pulse will justify us; for the pulse will often *justify* this treatment, though it will not *point it out*. We must frequently have recourse to the pulse;—not to learn what to do, but to learn whether it will sanction us in doing what other symptoms indicate to be a proper procedure. Whenever dropsy comes on suddenly (from the application of cold and wet), and the pulse will justify me, I certainly treat it as an inflammatory complaint. When the pulse is full, accompanied by a phlogistic diathesis, and signs of local inflammation, there can be no doubt about the treatment of the case.

In this form of the complaint, it is useless to employ diuretics; for the same reason that astringents are useless in active hæmorrhages from mucous membranes. If, however, we employ anti-phlogistic measures, the fluid will, in most cases, gradually disappear. Sometimes it does not; and then it is well, when we give purgatives, to exhibit those which are called "*hydragogue*;"<sup>a</sup> which cause very watery stools. In general, they will answer every purpose. Purgatives are exceedingly beneficial, in cases of inflammatory dropsy; for they not only act as anti-inflammatory remedies (like bleeding, in diminishing the bulk of the fluids) by causing a rapid secretion of fluid on the mucous surfaces; and thus, by acting upon the cause of the disease, tend to subdue the inflammation; but they act as palliatives, by causing the absorption of the effused dropsical fluid. It would be in vain to give diuretics in inflammatory dropsy; for they would not act during the inflammatory state of the system. Diuretics will not then act upon the kidneys; and the more the kidneys are stimulated, the less urine is secreted. But when we are giving hydragogue purgatives, we are doing the same as bleeding does; and, at the same time, we hasten the absorption of what has been collected; and in proportion as the inflammation is lessened, so do the hydragogue purgatives exercise more and more power over the kidneys. Among the best are elaterium, and a mixture of jalap and cream of tartar.

*Treatment of Passive Dropsy.*—If the dropsy be of *another* description,—being *without* any marks of inflammation,—low diet and bleeding will increase the collection tenfold. Here wine and perhaps good nourishment become necessary; together with steel, sulphate of quinine, and various diuretics. In this case the disease hangs on the patient so long, and such great inconvenience is felt from the collection of fluid, that, although diuretics will not *cure* the complaint, yet they are necessary for the purpose of lessening the quantity of fluid, which is collected in the body. Diuretics cannot go to the *cause* of the dropsy; they only tend to lessen the *effect* of the dropsy. Among the best are digitalis, calomel, squills, and acetate of potass; and it is very useful to give these in combination. When we

<sup>a</sup> From ὕδωρ, *water*; and αγω, *to drive out*.

cannot increase the dose of digitalis, or squills, we may that of the potass; therefore, by giving a great number of remedies, we do better than by trusting to one. We may give them to a full amount, by combining several together. The hydriodate of potass, and all the other salts of this alkali, are strongly diuretic.

*Mercury.*—The effect of diuretics is very much increased by the exhibition of mercury. In inflammatory dropsy, mercury is highly useful as a remedy against inflammation; but, in the opposite kind, it frequently would do harm by increasing the debility, especially if there were much organic disease; but given in great moderation, so as to produce a slight affection of the mouth, it will enable the other diuretics to act much more powerfully on the kidneys. Though we sometimes succeed in curing dropsy, by putting a patient under a profuse ptyalism, when all other things have failed; yet generally that is not the case, unless the dropsy is in some degree inflammatory, or unless there is inflammation of some organ; but, in all cases, the moderate administration of mercury increases the effects of diuretics.

When the chest is oppressed, and we find the patient in danger of suffocation; or when the abdomen is distended, and the patient suffers great pain; or when the cellular membrane is distended, so that a patient cannot move about; and we cannot wait for the cure of the dropsy itself, or of its cause (whatever this may be);—it would be right to have recourse to means calculated to get rid of the fluid as soon as possible. In these circumstances, violent purgatives (such as elaterium) in full doses, answer better than diuretics; and for this reason;—they cause a greater discharge; and they frequently go to the *cause* of the dropsy; and remove some obstruction, some congestion, or some inflammation. But, of course, diuretics may be given with the purgatives, to increase the effect. It is found useful to give diluents at the same time; for diuretics are frequently so very acrid, that they irritate the kidneys, much more than is necessary for secretion; and their operation is much facilitated by the patient's drinking largely of diluents. The same is observed with respect to purgatives. They seem to operate a great deal better, if plenty of diluents be taken at the same time.

*Mechanical Means.*—Sometimes patients are so oppressed with the fluid, that they cannot wait any longer. We find that our remedies does not remove it; and then we are obliged to have recourse to certain mechanical means for accomplishing this object. These are paracentesis<sup>a</sup> of the chest, or of the abdomen, and (in cases of anasarca<sup>b</sup>) the making of minute punctures in the skin, with a needle.<sup>c</sup> Some

<sup>a</sup> From *παραπνεύω*, to pierce through.

<sup>b</sup> From *ανα*, through; and *σαρξ*, flesh.

<sup>c</sup> The introduction of the needles is effected either by smartly pricking the skin, and pressing onwards, while the operator rotates the needle, or by a blow of a small mallet. Since the adoption of acupuncture by scientific practitioners, the following mode is preferred;—the spot being selected, usually the seat of pain, or (when any circumstance forbids this) the adjacent parts,—the operator, having stretched the skin with the fore and middle fingers of the left hand, pierces it perpendicularly with a gentle pressure; and the body of the needle is advanced by means of a semi-rotatory motion, in opposite directions, till it has penetrated to the required depth. This is repeated till the desired number is introduced. Their withdrawal is sometimes effected by means of a forceps; but it will be better to withdraw them by the same motion with which they were introduced, as the skin is painfully elevated by their direct and forcible retraction; possibly, also, by the latter mode, the point of the needle might be broken off, if it were not well tempered. The withdrawal of the needle is not followed by hæmorrhage; but sometimes a single drop of blood oozes from the puncture. In penetrating, the needle often meets with variable degrees of resistance;—according to the nature of the parts through which it passes. The Japanese and Chinese allow the needles to remain only while the patient makes thirty respirations. M. Cloquet states, that he derived the most marked benefit in cases where he caused them to be kept in several days; this accords with my own experience. It is true, the pain may cease instantaneously on the introduction of the first needle; but we observe this by far more frequently after the needles have been in some time. Indeed, so satisfied am I on this point, that I prefer a single needle remaining for some time in the part, to several introduced and withdrawn speedily. But there is yet no general rule as to the time which the needles ought to be allowed to remain. Dr. Baehæ—who has employed acupuncture successfully in America, in cases of rheumatism—states, that the more chronic (or long-standing) the disease, the greater will be the length of

persons scarify; but I am quite sure that every purpose may be answered with a fine needle. By making minute punctures in the skin, an immense quantity of water may be drawn away. There is no occasion to introduce the needle deeply; we have simply to put it through the skin, by rotating it between the finger and thumb; and when it is withdrawn, a bead of clear serum will appear; and the oozing will perhaps continue for some time. I have known it continue for days even after death. Twenty or thirty punctures may be made; and I never saw harm arise from the practice, when it was put in force above the knee. But although these punctures made with a needle are very minute, and the aperture is merely through the skin, patients have lost their lives through them. Gangrene has taken place even through this slight operation; but, in every case of this description that has come to my knowledge, the apertures had been made *below* the knee. It is an established rule in scarifying, to make the scarifications as high as possible towards the trunk of the body,—near to the most powerful parts of the body; and the same rule should be observed with respect to acupunctures. I have used them with great success all over the trunk, and upon the thighs, as low as the knees; and I have used them with equal success in all parts of the upper extremities; and I never met with any inconvenience. Before I was aware of the danger I frequently used them below the knee; and never once did any accident at all dangerous occur to me. Gentlemen, however, have related to me cases which came to their own knowledge, where the operation below the knee was dangerous;—where it was followed by sloughing of the skin; and, indeed, by sloughing of many muscles. One patient lost the gastrocnemii;<sup>a</sup> and, at the end of two or three weeks, his life.

These mechanical means are now and then necessary; but less frequently, if the disease be treated according as it is inflammatory or not. If we carefully determine the presence or absence of inflammation, we shall cure the complaint in a large number of cases. At St. Thomas's Hospital, when I have admitted a patient with the word "*dropsy*" on his letter, I have frequently been asked—"how I could admit such a case as that; since it was well known that dropsy could not be cured; and that Doctor Fordyce never admitted such cases." One of the greatest improvements in medicine, is that of distinguishing inflammatory diseases from those which are not so; and the establishment of the fact, that a great number of diseases are nothing more than so many inflammations. One half of the cases of dropsy which I see, are of an inflammatory nature; and yield to bleeding, and the other common remedies of inflammation.

time the needles should remain in the tissues. Practitioners who are best acquainted with the mode of performing the operation, object to forcing the needle in by sudden and direct plunging; because the tissues on its route are thus wounded; whereas, when the needle is gently rotated, they maintain that the fibres are only separated. In general, the pain of introduction is so slight, as to be entirely disregarded. As a proof of this it may be mentioned, that when M. Cloquet drew the attention of the profession to acupuncture, in Paris, it was by no means uncommon to see the students bare the calves of their legs, and insert common pins into the substance of the muscles; to convince the incredulous of the innocuity of the operation. Sometimes, however, the progress of the needle is marked by sudden and severe pain. M. Cloquet describes the pain as bearing some analogy to an electric shock. M. Dantu has made the same observation. (When the needle is of an oxidable metal, a galvanic current issues from it, and is recognised by the galvanic multiplier of *Schweigger*. But this circumstance does not appear to have any influence on the efficacy of acupuncture; which is equally successful when the needles are of gold, silver, or platina.) After the needle has been a short time introduced, it produces a sensation of pricking, heat, and in some instances cold and numbness; it is surrounded also by an areola, more or less vivid. Beclard saw one case, in which the introduction of a needle into the leg, to soothe acute pain, was followed by fainting and delirium. From the impression which it made on his mind, he felt disposed to reject the operation altogether. Fainting, however, must be of rare occurrence. M. Cloquet did not observe it oftener than once in thirty times, in the thousands of cases in which it was employed at St. Louis. In upwards of fifty cases in which Dr. Bache employed the needles, he did not observe a disposition to swooning in more than one case; in which, moreover, syncope did not take place; and in no case was any untoward consequence observed. Care should be taken to have the needles perfectly polished before using them; as the pain of introducing one that is quite smooth, will be comparatively slight. For this purpose, they should be passed into the emery-bag, both before and after use.

<sup>a</sup> From γαστήρ, the stomach; and κνήμη, the leg.

## CHAPTER V.

## DEFICIENT SECRETIONS.

SOME diseases are exactly the reverse of hæmorrhage, the profluvia, and dropsy;—being distinguished by a *deficiency* of secretion. In the height of inflammation, the ordinary secretion of the part may become scanty. Although it is increased at first, it will subsequently decrease;—usually remaining, however, beyond the natural quantity. Sometimes, in inflammation, the secretion is suspended. The secretions of the part itself, as well as the rest of the body, may be diminished under active inflammation;—"of the *part*;" for the condition of the secreting vessels in this state is incompatible with the discharge of their functions;—"of the *rest of the body*," from the disturbed state of the circulating fluids. This circumstance may occur, however, independently of inflammation. As in violent discharges, so we sometimes have, without inflammation, a perfect deficiency of secretion. This happens, in a most remarkable way, in the case of the kidney. Old men will sometimes cease to make water, not from any *retention* of urine, but from a *suppression* of it;—the kidney ceasing, or nearly ceasing, to secrete. In "*ischuria renalis*," as it is called, we have an instance of a case exactly opposite to that which occurs in the profluvia. The treatment of this particular disease will be given hereafter; I am now only speaking of these affections in general. We sometimes observe, on opening bodies, a similar state of the serous membranes. Sometimes the pericardium, and sometimes the pleura, is perfectly dry;—almost as dry as a piece of dried bladder. This is mentioned in many works on Morbid Anatomy. I do not know that this state induces any symptoms during life. According to Reynaud and Stokes, this condition of the pleural surfaces, gives rise to the peculiar *friction*-sounds in breathing, which mark the approach of pleurisy; but the state which is found after death, is precisely opposite to that which occurs in the affections of which I have just been speaking.

*Antagonism of the Secretions.*—[It is difficult for the student to understand the increase and decrease in the quantity of the various secretions, unless he possess some acquaintance with the laws of relation which exist between them.

"1. If one surface be more vascular and irritable than another in its neighbourhood, counter-irritation excited in the latter, will not diminish the morbid action in the former. An illustration of this principle is afforded in the example of conjunctival inflammation. If a blister be applied to the temple, for the relief of this state, it does not diminish the severity of the action; since the mucous membrane of the eye is more irritable than the neighbouring skin.

"2. An increased secretion of any given surface or structure, cannot be diminished by instituting an artificial discharge in some other part of the *same* tissue; because different portions of the same structure are related to each other by sympathy, and not by antagonism. Hence a copious secretion from the nose, will afford no relief to the conjunctiva under inflammation attended with discharge; nor will a disease of the mucous tract of the urinary organs be benefited by diarrhœa.

"3. Structures *dissimilar* in their offices antagonize each other; and the cutaneous secretion, therefore, may influence that of the kidneys. This is well known to occur; and augmentation of the one, is followed by a proportional diminution of the other. In extensive anasarca, the functions of the kidneys are almost entirely suspended; and suppressed cutaneous exhalation, is oftentimes succeeded by discharges from the intestinal and pulmonary mucous surfaces.

"4. When the functions of one organ exercise a positive control of those of another, it is observed that their respective secretions have some resemblance, with

respect to their effect upon the economy. The skin and kidneys *combine* to excrete *water* from the blood. Or the *vicarious* organ must be labouring under morbid predisposition; as when disease of the bronchi or intestine is excited by exposure to cold, and a general impression upon the surface of the body."<sup>a</sup>

These principles of correlation between the organs of the body, have been gathered from the physiological writings of Müller. They are, however, now generally recognised in the science of medicine.—*T. Williams.*]

## CHAPTER VI.

### CHANGES OF STRUCTURE.

INFLAMMATION sometimes produces changes of structure; and as I have spoken of those circumstances which merely affect secretion, or the escape of different fluids,<sup>b</sup> I now proceed to those which affect the substance of the body itself. Changes of structure, though frequently produced by inflammation, and frequently connected with inflammation, are sometimes (like hæmorrhages, dropsies, and the profluvia) *not* connected with it. They are, in the first place, changes of *consistence*, and changes of *size*; in the next place, transformations,—in which the substance is changed in its *nature*; and thirdly, new formations,—in which something new appears, totally different from what we see in the body naturally. Two, or even all three of these changes, may occur together. The first of which I shall speak, and which are more frequently the effect of inflammation than not, are changes of consistence, and changes of size. With respect to changes of *consistence*, I need not say that they can only be two;—hardening on the one hand, and softening on the other. I shall first speak of induration.

#### SECTION I.—INDURATION.

*Turgescence.*—It is to be remembered, in the first place, that induration may be only apparent. An organ may feel much harder than natural,—may be really harder; and yet we are justified in saying, that the hardness is only apparent. I will explain this. If there be extreme congestion in a part that can expand, it will become larger, and feel much harder than natural. If there be an obstruction to the flow of blood from the liver, though the proper structure of the liver itself will only be of its natural hardness, yet, in consequence of the obstruction, it will feel exceedingly hard; but, on liberating the blood, or making an incision, and letting the blood escape, it will come down to its natural consistence. This affection may be induced by an obstruction during life; and I believe that the same thing may be induced after death, by a violent injection of fluid. We must therefore consider, when we see a part indurated, whether it is organic induration, or merely a state of great turgescence, or repletion, in consequence of an excess of fluid.

*Organic Induration.*—When a part is really hardened, it is generally pale. Of course, if the hardness be merely dependent upon the collection of blood in the part, it will be of a deeper colour than usual; but if the part be organically hardened,—if it have undergone a hardening process, it is generally paler. As the part is more compact, we must suppose that, in general, the diameter of the blood-vessels will be less; and, therefore, there will not be such a proportion of blood as there was

<sup>a</sup> Müller's "Physiology;" Second Edition; Volume 1; Page 518.

<sup>b</sup> See Chapters 2 to 5; Pages 136 to 176.

before. Sometimes the hardened part acquires a new colour. It may be gray, yellow, brown, or even black; but, for the most part, a portion of the body which has become indurated, is paler than usual. It does not follow, because a part has become indurated, that the size should be altered. A part may be hardened; and it may be larger or smaller than before; or it may retain its natural size. We have (every day) instances of induration, in the case of a fistula along the side of the rectum, and in "fistula in perinæo." The parts we find here may be all exceedingly hard. The heart is not unfrequently in this condition; for though this organ is more frequently affected in *size*, we not unfrequently find the heart hard. Even the general cellular membrane is frequently seen hardened; and especially in young children.

*Cause of Induration.*—This process of hardening is, for the most part, slow; and is generally the effect of chronic inflammation. Sometimes it does not occur till the inflammation is entirely over;—till the part has become pale, and there is no reason to suppose that inflammation exists; and then that process will take place, by which the part becomes hardened.

[It is important to establish that distinction between induration and hypertrophy, which is indicated by the essential difference in the actions upon which they respectively depend. The former necessarily owes its origin to inflammation; the latter is the result of an increase in the natural assimilative powers of the part. To consider intimately the process of induration, it must be remembered that the *slowness* with which the product of the chronic inflammation is effused, allows sufficient time for the absorption of the fluid portions;—thus leaving the cells of the tissue to be occupied by the hardened fibrin exclusively.]

This view of its production immediately suggests, that the mode in which counter-irritation frequently either softens or removes the induration of parts, consists in exciting a more active inflammation; which, by its rapidly effused product, liquefies the hardened material, and thus renders it absorbable. In induration, then, the albuminous and fibrinous portions of the blood accumulate, unassimilated, in the primitive cells and between the particles of the tissue. The material, therefore, upon which the hardening of structures depends, is always the same, however dissimilar the composition of the latter. That the process of inflammation, however, is intimately modified by the organization of the structure in which it occurs, appears obvious from the fact, that mucous membranes never undergo the hardening process. Nor could such a change be *à priori* expected; for it is well known, that inflammation in them is seldom marked by the effusion of albumino-fibrin; and this further accounts for the fact, that mucous surfaces are never agglutinated by common inflammation. From these observations it at once appears, that if the liquor sanguinis, in this simple and chronic action of hardening, were altered by disease in the blood, it may give rise, by assuming modified forms, to various malignant and non-malignant affections;—the deposition of tubercles, carcinoma, melanosis, and so forth, may be the result. These, however, will be separately considered. In reference to this state, Dr. Carswell<sup>a</sup> remarks:—"Induration differs from the solidification in acute inflammation in this;—that there is, at the same time, increased cohesion of the anatomical elements of the affected part. Tissues, instead of being more easily separated (as in the former state), are more firmly united, or so often confounded together as to have lost their distinctive characters; and soft, spongy, or cellular organs, frequently acquire a very great degree of density and tenacity. It is obviously the consequence of the organization of the coagulable lymph effused, in the *second* stages of acute inflammation, either into the interstitial cellular structure of the organs, or into the tissues themselves, in the state of softening induced by the *first* stages. It is always accompanied by the gray discoloration of chronic inflammation, and by a greater or less degree of opacity of the membranous tissues." For a valuably

<sup>a</sup> "Pathological Anatomy.—Illustrations of the Elementary Forms of Disease. By Robert Carswell, M. D." &c.

practical account of inflammatory changes, we direct the reader to this splendid work of Dr. Carswell.—*Thomas Williams.*]

*Treatment.*—When there is no inflammation, the affection is best removed by irritating the part. If the hardening be evidently attended by inflammation, antiphlogistic remedies are the best that can be adopted. Bleeding, both local and general, together with mercury, iodine, fomentations, poultices, friction, and pressure, are particularly proper. But sometimes there is no inflammation to be discovered; and then stimulation of the part answers much better than any thing else. It is also of great use to excite a discharge from the part itself, or close to it. It will frequently cause an absorption of the excessive matter which has been deposited. Occasionally, when there is no inflammation to be discovered, the treatment of induration becomes so irritating, that inflammation is set up; so that inflammation, although it may at first have laid the foundation of the disease, and produced it, yet afterwards has ceased; and then comes on again, as a third stage.

## SECTION II.—SOFTENING.

The opposite to this change of parts, is softening; called by the French "*ramollissement*;" which means nothing more than "*softening*." Formerly this change was very vaguely described. Even induration was commonly described as a termination of inflammation, by the name of "*scirrhus*;"—*scirrhus* being confounded with simple induration. The process of softening is remarkably seen in central parts of the nervous system; and also in the alimentary canal. The mucous membrane of the stomach and intestines, is frequently reduced to a mere pulp, which may be brushed off with a slight touch of the finger; and sometimes it appears to be removed even before death. In the case of the brain, we (every day) see that organ reduced, in certain portions, to a mere soft paste. It occurs, also, in the skin;—sometimes in the epidermis, sometimes in the cutis itself, and sometimes in the nails. We must all have seen the nails so softened, as to appear more like wet card than any thing else. This softening will affect the cellular membrane; and then it will allow the serous membrane without the intestines (for example), or the mucous membrane within, to be peeled off. If we can peel off the peritonæum from a portion of the stomach and intestines, it must be from the subjacent cellular membrane having become so softened, that the serous membrane is no longer attached. So, if we can peel off portions of the mucous membrane, it must be from the sub-mucous cellular membrane having become so softened, that it is no longer properly attached. The cellular membrane will sometimes remain solid, while all the other parts are excessively softened. This is seen in the case of the brain, for example, and of the spinal marrow. They will become soft; while the pia mater (which corresponds with cellular membrane) immediately upon the brain, and immediately upon the spinal marrow, will be perfectly firm. A serous membrane, such as the peritonæum, will sometimes soften; as also will arteries, and even cartilage, and bone itself. Bones may show such a disposition to become softened, that one species of disease has acquired the particular name of "*mollities ossium*;" and in rickets,—another disease of the bones,—they are much below their natural consistence. The muscles, too, will sometimes become soft. After a person has been long exposed to the operation of lead, in painting, I have seen the muscles become much softer than natural; and so pale, as to look like any thing but muscles. The heart itself, like other muscles, will frequently become soft. Sometimes the finger may be pushed through its parietes, in consequence of the excessive softening which occurs. But every structure in the body may become softened. When parts are softened, they frequently retain their natural colour; but sometimes they are paler than they should be: sometimes they are redder; and sometimes they become brown and dark. There are great varieties with regard to colour; both when a part is indurated, and when it is softened. The colour may be unaltered; or it may be paler than natural (which is generally the case), or it may be deeper than usual.

As with induration, so with softening, a part may sometimes acquire an augmented volume; or it may become smaller; and sometimes its bulk remains unaltered. You would not suppose that a part could be very rapidly softened; and yet it is certain that a part may be softened in a very short time;—at least, for myself, together with many French writers, and perhaps others, I feel satisfied that that is the case. It is mentioned by the French, that a few days, if not a shorter time, are sufficient to produce a pulpiness of an organ, which before was apparently in a state of health. I think I have seen sufficient to make me believe that, in an acute disease, an organ (previously sound) may lose its natural firmness, and become a mere pulp, in a very short space of time. This result is unquestionably due to the solvent power of the inflammatory product upon the component tissue of the organ; combined with the pressure which, by distending the cells, it exerts upon their walls;—thus impeding and suspending their nutrition.

Induration is generally the effect of chronic inflammation; and softening, in some circumstances, arises from the same source. But I have seen a person in tolerable health suddenly, without any evident reason, fall into a state of the greatest debility;—with most complete prostration of strength; with no pulse; and, in two or three days, some organ or other has been found reduced to a pulp. I had great doubts, when I first noticed this, of the accuracy of my observation; but on reading the French writers, I found that they detailed cases exactly similar; and that they came to the conclusion which I felt inclined to entertain, though not without hesitation. When very rapid, I do not believe it is always the result of inflammation, or is even inflammatory; and when a slow process, I am sure it is not always inflammatory; for the parts are often exceedingly pale. In rickets (or *mollities ossium*), what inflammation is there of the bones?

[This change, which consists in the softening of structures, has been more accurately examined in the brain than in any other organ; and, since the process is essentially the same in every structure, the brain may be allowed as the type of softening in other parts. Dr. Hodgkin<sup>a</sup> instances the brain of a child affected with hypertrophy, to illustrate the dependence of *ramollissement* upon excessive growth; for the texture of the brain, under this rapid nutrition, has not acquired the firmness which interstitial deposit may give.

It is, however, pathologically important to distinguish between the one,—which is only an excessive process of growth; and the other,—which unquestionably is distinct from, and injurious to, the process of nutrition when associated with inflammation. Dr. Symonds,<sup>b</sup> in reference to this point, coincides with the above opinion; and declares that softening, as a disease of nutrition, is (compared with that which results from inflammation) of infrequent occurrence.—“When softening is due to inflammation, the fluid effused, in most cases, not only breaks down the structure by infiltration, but also by its *pressure* impedes the nutritive deposition. But when softening presents itself as a true perversion of nutrition, we find the tissue in one of two states;—either those molecules which impart the usual degree of firmness are deficient; or, when the tissue is less composite, the ultimate molecules are softer than natural.”—It is now generally admitted, by morbid anatomists, that the colour of the softening is regulated by the previous amount of blood in the part;—the transition of the part, however, from one colour to the other, after the commencement of inflammation, will depend upon changes in the effused matter. When redness of a part is at first intense, the colour of the resultant softening is permanent, until suppuration occurs; when it successively assumes a chocolate-brown, green, or gray colour. If the lungs or brain be the seat of these successive changes, each state receives distinctive appellations. In the lungs they are known, in the language of Andral, as the “*ramollissement rouge*” and “*grise*,” in that of Laennec, as “*hepatisation grise*,” and in the brain they are recognised under the epithets, “red” and “yellow softening.” Abercrombie<sup>c</sup> has described a white or

<sup>a</sup> “Cyclopædia of Surgery,” Page 200.

<sup>b</sup> “Library of Medicine,” Volume I; Page 40.

<sup>c</sup> “Pathological Researches on the Brain and Spinal Cord,” Part I. Section II.

colourless softening, in which the cerebral matter is curdy and glistening. This change he states to depend upon inflammation; and instances the *corpus callosum*, the *septum lucidum*, and *fornix*, as its frequent seat.—*Thomas Williams*.]

*Cadaveric Softening*.—I have mentioned,<sup>a</sup> that every case of *apparent* induration is not to be considered *real*; for it may depend upon great congestion. From the presence of fluid, a part may acquire increased bulk and firmness. But softening cannot be merely apparent. If a part be soft, there can be no deception in it. It is necessary, however, to guard against an error on this point. Softening may occur after death; and merely because, on a *post-mortem* examination, we find a part excessively softened, it is not to be concluded that it was in that state during life. Parts will become softened from decomposition;—they will melt down to a reddish pulp. I mentioned, when speaking of redness, that a red appearance is sometimes mistaken for inflammation;<sup>b</sup> whereas it may be only the effect of a red fluid which transudes, and encircles and dyes the part. Parts will become softened from decomposition. The brain, without any morbid state, very speedily becomes soft. Every body knows, that if he wishes to dissect a brain well, he must have it fresh;—that if the person has been dead any time, or the brain has been exposed to the air, it becomes too soft for accurate dissection. But the fluids within the body will themselves sometimes dissolve parts. There can be no doubt that the gastric juice will produce a softening of the interior of the stomach; and even do more than that. It will soften the whole coats of the organ, escape into the cavity of the peritonæum, and soften whatever it comes near. This was discovered by John Hunter; and I think we have sufficient proof of the accuracy of his observation. The appearances thus arising from the gastric juice, have sometimes led persons, who were ignorant of the fact, to imagine that a patient had been poisoned.

*Effects of Softening*.—I need not say that, when softening occurs during life, it must produce some effect. A large number of cases of paralysis, depend upon a softening of the brain, or of the spinal marrow. Some case of fatuity, likewise, depend upon a softened state of the anterior portion of the brain. Sometimes extreme debility supervenes, when any essential organ (such as the liver, the lungs, or the heart) becomes softened. Except in bones, and parts at or near the surface, the existence of this softened state cannot, of course, be well known during life. We only infer it as probable.

*Treatment*.—Induration, I have stated,<sup>c</sup> may in certain cases be removed by the remedies of inflammation; while, in others, stimulants will frequently cure it; especially if aided by mercury. But it is not known whether a softened state of a part can be recovered from. Indeed it is extremely difficult, if not impossible, to restore the consistence of an organ, after it has been reduced to the state of pulp. If the part show signs of inflammation, the only treatment is that appropriate for inflammation. It is difficult to know that the part is softened; it is only seen to be inflamed. In cases of paralysis, we cannot tell that the part is softened; but when symptoms of violent pain at one part of the head and great heat occur, and the patient gradually becomes paralytic, there is a probability that the part is softened; but still no proof of it is given. If signs of inflammation be observed, they must be treated;—without regard to softening or induration. If prostration of strength come on, it must be our endeavour to remove it;—not knowing whether the parts are softened or not. In the case of the heart, extreme feebleness of its stroke, when examined at the chest, is frequently found.

### SECTION III.—HYPERTROPHY.

The foregoing are changes with respect to *consistence*; we have others with respect to *size*. If a part really obtain an addition of substance, not dependent on

<sup>a</sup> See Page 176.

<sup>b</sup> See Page 60.

<sup>c</sup> See Page 178.

transformation, or a new formation, it is said to be *hypertrophied*. This is a new word; but it is a very convenient one. The part suffers an excess of nourishment; it is therefore hypertrophied,—over-nourished.

[An important principle, regulating the formation of all organized textures, has been brought to light by the microscopic labours of Schwann and Schleiden, in Germany. They found, that in the production of any given form of tissue,—such as fibre or tube,—nature does not at once unite the organic molecules in that form; but first creates, by a definite process, “round vesicles or cells,” and subsequently transforms these into the various elements of the organic textures. By the adaptation of these views it can be shown, that nutrition exemplifies the fundamental principle of organic assimilation;—each elementary particle attracting similar particles from the blood, in order to maintain the integral organ; and, by the changes thus impressed upon them, they are caused to participate in the vital principle of the organ itself. Under the head of “induration,” however, it has been already remarked,\* that organs may increase in size, independently of inflammation. In this state, the albumen and fibrin of the blood accumulate, unassimilated, between the particles of the tissue. In proper hypertrophy, however, the assimilative action continues, and at an augmented rate. The uterus, in the pregnant state, increases in bulk by the addition of real contractile particles, duly assimilated to the original tissue. But inflammation is not an increase of the plastic, or nutritive process; although its products are susceptible of organization. In hypertrophy and inflammation, “nucleated cells” are equally generated in the effused material. These cells may undergo no further transformation: and, with the fluid in which they are contained, may constitute pus; or they may proceed to assume the form of fibres. But the tissue which thus results is always the same, whatever may be the structure of the organ in which the inflammation is seated. In parts which are undergoing hypertrophy, however, though the nutritive matter effused assumes at first the form of nucleated cells, each tissue exerts a different assimilating influence upon it; and causes the transformation of the cells into structure of its own kind, whether fibrous or cellular.—*T. Williams.*]

*Nature of Hypertrophy.*—Hypertrophy may affect one elementary tissue of an organ only; or it may effect the whole of an organ together,—every tissue of which it is composed. It will sometimes affect the cellular membrane; and then this becomes thicker and perhaps denser than it should be. A part may be over-nourished, without increasing its size. The excess may be such as merely to harden it; so that, in one sense, induration may be an hypertrophy. But, very generally, when a part is over-nourished, it acquires a considerable excess of bulk. If the cellular membrane be over-nourished, and at the same time indurated, dead-white lines, or semi-translucent streaks, are seen along it. Frequently, only portions of it fall into this state of excessive nourishment. There may be produced tumours which, when cut, resemble a turnip in consistence, and in which white and grayish fibres are seen. This is the character of scirrhus; and there is a doubt among those who cultivate morbid anatomy, as to whether this ought to be called a new formation; or is merely an excessive nourishment—hypertrophy and induration—of the cellular membrane. But however this may be, when the cellular membrane is thus affected, it presents dead-white, or semi-translucent lines; and it may form a tumour in one particular spot. Sometimes the cellular membrane, in this state, on being cut, will resemble lard, or imperfect cartilage.

*Tissues and Organs liable to Hypertrophy.*—Mucous membranes are frequently hypertrophied. The villi of the intestines are sometimes very much enlarged; the mucous follicles are likewise enlarged; and the whole are increased in size. The skin frequently suffers this change;—becomes excessively indurated and thickened. The brain will sometimes be hypertrophied; though I never saw more than one instance of this affection. I have seen many instances of partial induration, and cases where all the brain was very firm; but there was nothing except a hardening

\* See Page 177.

of the organ. In this instance, however, the brain had become larger than it should be. It caused the skull to be very much beyond the usual dimensions; and looked, on opening the skull, as if it had been ready to burst it asunder. The convolutions were all very large. This is a state described by many authors; and, for the most part, fatal disease of the brain is at length produced. This patient—a lad, who was exceedingly precocious—had a head larger than a man's. His character corresponded with that of an adult; and he suddenly became apoplectic and hemiplegic, and then died. Nothing was to be found but an excessive size of the organ;—the brain, in other respects, being healthy.

The spinal marrow has been seen hypertrophied. Nerves will fall into this state after amputation. The nervous ends will become very large; and frequently there is a morbid sensibility. Muscles are sometimes seen hypertrophied; but the organ most frequently thus affected is the heart. The most common disease of the heart, is excessive nourishment of some portion; and that portion is, by far most frequently, the left ventricle. Blood-vessels, as well as the heart, will become hypertrophied; vessels are sometimes only accessorially hypertrophied; vascular tumours may likewise occur. On examining these tumours, we find nothing but a congeries of blood-vessels. Some tumours of this description have been called "*fungus hæmatodes*;" but such an appellation leads to a confusion of terms. By "*fungus hæmatodes*" we more particularly understand a combination of this state with a deposition of encephaloid (brain-like) substance.

*Changes in Size accompanying Hypertrophy.*—When a part is over-nourished, there is usually (I said\*) an increase of bulk. But an excess of nourishment may go only to condensation; and then a change of size does not occur, but only a change of consistence; and sometimes an organ which is partially over-nourished, may be smaller than usual. It will sometimes happen, when an organ is composed of more tissues than one, that one tissue will entirely waste; and the wasting of the one, may more than counterbalance the over-nourishment of another. With respect to the cavity of an organ so hypertrophied, it may sometimes be seen diminished, sometimes increased, and sometimes unaltered. That occurs in the case of the heart. Sometimes, if the heart be hypertrophied, the cavities enlarge; but sometimes the deposition of matter takes place outwards, and the heart really is enlarged, but the cavity remains much the same. Occasionally, however, the deposition takes place inwards; and the cavity becomes greatly reduced. When a part is thus hypertrophied, the consistence sometimes remains the same; sometimes it is increased; and sometimes it is diminished. There is just the same variation in colour. Sometimes the colour remains natural; sometimes it is paler; and sometimes it is heightened.

*Causes.*—I believe that hypertrophy of a part is generally, more or less, of an inflammatory nature. Certainly, that is the case with the heart. Hypertrophy of the heart is, in most instances, entirely of an inflammatory nature; and, indeed, it may be supposed that an excess of nourishment must be the result of an excessive action in the part itself;—it must be supposed, therefore, that all the natural processes of the heart are going on with tenfold vigour. If a certain operation be necessary to the continuance of nourishment, and it is much increased, an excess of nourishment will be afforded. It is impossible, in a great number of cases, to consider hypertrophy as any thing more than a sort of inflammatory state. Excessive exercise of a part, however, will sometimes cause it to be over-nourished. We know that muscles will increase by exercise. A great excess of action in a part, will sometimes cause it to acquire a bulk much beyond its natural dimensions. Still this is excessive excitement. It is *chronic* inflammation which causes hypertrophy; *acute* inflammation rarely does,—except so far as it lays the foundation for hypertrophy. Andral mentions, that hypertrophy may sometimes arise from a defect of absorption;—that the absorbents do not carry away the materials that they ought. An accumulation of nourishment takes place, without undue nourish-

\* See Page 181.

ment being deposited. This, however, is but a mere hypothesis. He calls it a want of de-assimilation;—the want of removal of those particles which are already deposited, and have served their purpose.<sup>a</sup>

*State of General Health in Hypertrophy.*—When a part falls into this condition of hypertrophy, it is necessarily in a state of excessive activity,—though perhaps without strength; and, indeed, no mark of inflammation may be discernible. Persons of the most sickly character, are frequently subject to this affection; as in those unhealthy parts of the world where bronchocoele exists;—where the thyroid gland falls into a state of hypertrophy. Individuals in those situations are, for the most part, in a state of delicate health;—sallow,—shrivelled. So, in rickets, the ends of the bones enlarge very much;—they are hypertrophied; but the case is one of debility. In scrofula, we frequently see parts become enlarged. The ends of the fingers, in a case of decided scrofula, are oftentimes much enlarged; the mesenteric glands, and also the upper lip, are much larger than they should be; and yet such persons are not instances of strength, and of increased vigour. Indeed, in the most unhealthy districts, (the valleys of the Alps, for example,) hypertrophy—not only of the thyroid gland, but also of the liver, the tongue, the bones, and the hand—frequently happens; and yet the persons are pale and emaciated, and no sign of inflammation appears. Hypertrophy may induce very serious effects in the case of the brain. I believe that sooner or later apoplexy, paralysis, or epilepsy, will ensue. In the case of the heart, very great suffering is induced. There is palpitation from the slightest causes; there is, generally, a strong violent pulse; and, at last, there is dropsy.

*Treatment.*—The usual remedies for hypertrophy, are the general remedies for inflammation;—rest and low diet, with moderate and repeated bleeding. But occasionally these measures are not justifiable; and the strength must then be supported. Of course, when this affection occurs in a cachectic habit of body, (as rickets, or scrofula, or the state of cretinism in the Alps,) any thing that depresses the powers of the body may do harm; and good air and good food are the best remedies.

#### SECTION IV.—ATROPHY.

The opposite of hypertrophy is atrophy,—wasting. Sometimes the part which wastes does not become smaller, but becomes thinner than usual. Its bulk may be the same; but its texture may become lighter,—more spongy than usual. Atrophy sometimes affects the whole of an organ; sometimes only a portion, or a tissue; and sometimes the part will become thinner and thinner, till at last it is perforated. Parts that waste away are generally softer, and frequently paler than natural. Atrophy of parts is commonly induced by inflammation, or by violent irritation. The excessive nutrition of neighbouring organs, will frequently cause one to waste;—the excessive action going on in one, causing the actions of the other to decline. A wasting away of the testicles, frequently supervenes on inflammation which has followed the mumps. Andral mentions that, after suppuration near the liver, he saw the gall-bladder waste away entirely.

<sup>a</sup> Dr. Carswell, in his "Illustrations of the Elementary Forms of Disease," resolves the causes of hypertrophy into three:—

- "1. The frequent and increased action of an organ in the exercise of its function.
- "2. The existence of a mechanical obstacle to the accomplishment of the function of an organ.
- "3. The long continued influence of a morbid stimulus."

The first is exemplified in the hypertrophic growth of the voluntary muscles, from frequent and excessive action. Examples of the second are presented to us in the enlargement of the walls of the hollow viscera, from obstruction to the ready escape of their contents;—the heart, stomach, and bladder may be enumerated. Long and chronic inflammation, and irritation of a part, would induce the third. Elephantiasis, and other similar affections of the integuments, are the best illustrations.—*T. Williams.*

*Causes.*—Atrophy is frequently an effect of bad air, bad food, depression of mind, or deficient exercise. As we must consider hypertrophy in general to be *excessive* function, so in atrophy there is diminished action, a *deficiency* of function.<sup>a</sup>

*Treatment.*—As it is usually the very opposite state of things from hypertrophy, very opposite remedies are usually required. So far from the part being allowed to be at rest, it must be well used, if possible; and must also be stimulated as far as may be.

## CHAPTER VII.

### TRANSFORMATIONS OF STRUCTURE.

I now proceed to consider those changes, in which one structure is converted into another structure, natural to the body. These are called “transformations.” Though of a diseased character, they are like those which naturally occur, during the growth and decline of an individual in health; or else they are the structures of which the particular part is actually found to be naturally composed, in some orders of the animal series. The cellular membrane is the frame-work of the other structures of the body; and, in the natural condition of the body (that is, in its natural progress), we observe that when a part is no longer wanted, it degenerates into cellular membrane. An instance of this is presented to us, in the thymus gland of the fœtus. Now such a change will occur merely as a diseased process. A part may be resolved nearly into cellular membrane; and that is an instance of transformation. Cartilage will sometimes, by disease, become bone; but it is perfectly natural to the progress of the body, that cartilage should become bone in the fœtus; for cartilage precedes the formation of bone, although recent physiologists state, that there are distinctive marks by which the primitive cartilage may be distinguished from that which subsequently forms the basis of the bones. For the most part, then, the morbid changes which are transformations, are nothing more than alterations, precisely the same as those which happen naturally in the progress of the human body; or they are alterations of a part to a structure, natural to some other animals. Although they are morbid processes, they observe exactly the same law as those which are natural. One structure is not changed into another, unless that same structure is observed to be naturally changed into that other, at some period of the progress of the body; or unless that other is the natural structure of the part, in some other of the series of animals. Cartilage, I have said, will become bone through disease; and the same is observed as a natural process at certain ages; whereas it is never known that, by any disease, a mucous will become a serous membrane. As such a change is unknown in physiology, so it is unknown in pathology.

Mucus membranes may be converted into skin, and skin may be converted into mucous membranes; muscles will also degenerate into fibrous membranes. Now

<sup>a</sup> Dr. Carswell views this organic change as owing its origin to causes which are the converse of those inducing hypertrophy:—

1. Atrophy from a diminished supply of blood.
2. Atrophy from the diminished exercise of the function of innervation.
3. Atrophy from the diminished exercise of the functions of an organ.

The first kind is exemplified in the diminution of bulk which takes place in the brain, after ossification of the carotid and vertebral arteries of one side. Atrophy of the testicle results from the obliteration of the spermatic artery; of the spleen from the closure of the splenic artery; and so on.—The second is illustrated in cases of paralysis.—The third variety is shown in the effects of artificial anus;—the intestine beneath or beyond being reduced to a transparent membrane. Or when one of the bronchial tubes is obliterated, the lung beyond atrophies.—*T. Williams.*

the very same part which is mucous membrane in one animal, is skin in another; and what are muscles in some animals, are merely fibro-ligamentous substances in another. These same changes, however, will occasionally take place out of their natural course, through disease; and they are then called "transformations." Cartilage, on the other hand, is never known, in physiology, to become mucous membrane. What is cartilage in one animal, is never mucous membrane in another; and in the transformations which take place in the progress of the human body naturally, cartilage never becomes mucous membrane. So in disease, cartilage is never known to be converted into a mucous membrane.

*Cellular Transformations.*—Almost all the structures of the body will waste into *cellular membrane*. It is perhaps hardly right to say they are *transformations* into it; because cellular tissue is the frame-work of all the other structures. Indeed, it has been said, that if all the various other substances were absorbed, and nothing but the cellular substance remained, (provided it could be kept firm,) it would maintain the entire form of the body. Parts often appear to be transformed into *fat*; but Andral considers that this is merely an instance of inordinate secretion of fat, with or without atrophy of the tissues.

*Membranous Transformations.*—We have frequently a transformation to *serous membrane*. When the extremity of a bone has been dislocated, it will be found, after a considerable lapse of time, that a serous membrane is formed around it. If a coagulum of blood be effused into the brain, or any other firm substance (even a bullet) be deposited there, it will become surrounded by a serous membrane (a "capsule," as it is called); which secretes serous fluid. Occasionally, when there is a loss of substance which nature cannot entirely repair, the space is enveloped by a serous membrane. Even when a portion of substance is deficient, not by external violence, but by a natural defect, its place is frequently supplied by a serous membrane. In a defect of portions of brain, we find in their room a bag, containing liquid; which bag is, to all intents and purposes, a serous membrane. What are called "apoplectic cells" in the brain, are nothing more than cavities formed by a coagulum of blood which has been effused; and which coagulum has had a serous membrane formed around it. The coagulum will be absorbed, while the serous membrane may remain, and continue to secrete fluid.<sup>a</sup>

Such cysts may be formed in almost any part of the body. A serous membrane is a closed sac, with a smooth internal secreting surface; and is found in the body naturally. Precisely such sacs are formed by disease; and are of all sizes;—from that of a pin's head, to a very considerable bulk. We find these cysts sometimes placed in *juxta-position*, either attached or unattached to each other; and sometimes they are closely united to the surrounding parts. They may be single, or they may be numerous,—solitary, or crowded. Generally there is no red vessel to be traced beneath the external surface; and the utmost vascularity is an arborization upon this. The part which surrounds these cysts is found in different states. Usually it is perfectly healthy, sometimes it is wasted, and sometimes it is in other

<sup>a</sup> It is remarked by Müller, and Heule, that the adventitious membranes, which are produced in the lungs to line vomical cavities, and in the brain to circumscribe a clot of blood or a collection of matter, although presenting a smooth surface internally, are notwithstanding wholly unlike serous membranes in organization. Delpech and Mr. B. Phillips and others state, that these artificial membranes consist of nothing more than a condensation of the surrounding tissue, from infiltration of its cells. Bichat, however, declares that all cysts are analogous in structure to serous membranes; but this statement is found, by all subsequent writers, to be incorrect. But, further, these cysts may undergo a variety of changes, without any conformity with the law expounded in the context by Dr. Elliotson. The factitious lining of morbidly produced bursæ, and all diseased cavities, irrespectively of their contents, may indiscriminately be transformed into an osseous or cartilaginous substance; or hair may even grow in the most unnatural situations, and from the most different structures. These, in addition to other physiological reasons, would induce me to question the accuracy of the law of transformations, sought to be established by the author. It is certain, that many transformations of which no type or analogue can be found, either in inferior animals, or in the earlier stages of man's development, frequently occur from diseased action.—T. Williams.

states of disease; as, for example, in a state of induration. Occasionally we find these cysts surrounded by pus, or some other secretion. They are frequently surrounded by cellular substance, which gives them an additional coat; sometimes they become indurated,—even to cartilage or bone; and sometimes they become more or less fibrous. The cellular membrane becomes very firm round the fibrinous cup of an abscess, and gives it an additional support; and so it is with respect to these serous cysts. The cellular membrane around them is frequently condensed.

*Interior of Adventitious Cysts.*—The internal part of these cysts, presents very different appearances. Occasionally, and indeed for the most part, it is smooth,—exactly as in a natural serous membrane; but it varies, just as natural serous membranes do when diseased. When natural serous membranes are diseased, they are frequently rough, granulated, or flocculent within; and so the interior of these adventitious membranes presents a great variety of appearances;—being occasionally rough, with minute granules; and sometimes with large caruncles, as it were. The granules which adhere to the interior of these cysts, are frequently of an osseous character; or contain, at least, more or fewer particles of bone. Occasionally we observe false membranes lining the interior of cysts; that is to say, fibrin has been poured out;—giving them exactly the appearance presented by inflamed serous membranes, and of which I spoke formerly.<sup>a</sup> There are frequently partitions in these cavities,—dividing them into compartments. Frequently there are prolongations from the interior, running through the cavity of the cyst, and not completely dividing it; but causing it to have a number of compartments, communicating more or less with each other.

*Contents of Cysts.*—The contents of these new serous membranes, as well as their internal surface, are very various. Occasionally they contain merely a serous fluid;—occasionally they contain blood. They will contain something like mucus;—various saline matters, fatty matters, tubercular matter, and some things which are peculiar to cysts. There is a far greater variety in the contents of these serous cysts, than in those of the natural serous membranes of the body, when the latter happen to be diseased. Different substances may be found in different portions of the same cyst. We may also find some cysts growing from the inside of others,—hanging in them by peduncles; and sometimes, instead of hanging in this manner, they are attached to the interior by a flat surface of considerable extent.

*Hydatid Formations.*—It has been imagined, that all the new formations of the body are originally nothing more than cysts; and these cysts have been called “hydatids.”<sup>b</sup> The term “*hydatid*” should be confined to a certain animal; but it is used vaguely to embrace, not only real animals, but also these serous cysts; which are nothing more than morbidly formed serous membranes. It has been imagined, that all the new formations of the body were originally hydatids;—that is to say, either parasitic animals, or such new cysts as I have mentioned. One compartment of these cysts, it is true, will sometimes be filled with scirrhus matter, another with melanotic, and another with encephaloid; and we continually see minute serous cysts by the side of scirrhus, melanosis, &c.; whence it has been supposed, that these are merely different stages and forms of the same disease. But I do not see any proof of it; for when a part has once fallen into a state of disease, all kinds of disease will frequently spring up around and in it. Where we cannot detect any new serous membrane, but where we see the solid substance of scirrhus (for example), it has been supposed, that it was originally nothing more than a serous cyst, filled with indurated substance;—that the transverse bands are nothing more than new serous cysts, which grew on the inside, and hung by peduncles; and which became filled with an indurated substance, until the whole formed one mass;—that the fibrous bands we see in scirrhus, are nothing more than different serous cysts, all compacted in this way. On this subject, the works of Dr. Baron;<sup>c</sup>

<sup>a</sup> See Pages 108 and 109.

<sup>b</sup> From ὑδαρ, ὕδωρ, water.

<sup>c</sup> “Inquiry, illustrating the Nature of Tuberculated Accretions,” &c. (1819); “Illustrations of the Inquiry,” &c. (1822); and “Delineations of the Origin and Progress of Various Changes of Structure,” &c. (1828).

and a paper by Dr. Hodgkin, in the "Medico-Chirurgical Transactions,"<sup>a</sup> may be consulted. Their views are ingenious; but whether altogether true, I will not pretend to say. Dr. Hodgkin followed Dr. Baron; and, as far as I can comprehend his paper, has only developed Dr. Baron's views.

Minute sacs, as observed in various parts of the body, are usually nothing more than new serous cysts. They are continually met with in the choroid plexus of the brain; and they are seen of all sizes;—from the most minute, till they attain a very considerable magnitude.

*Mucous Transformations.*—With respect to the transformation to *mucous* membranes, when a natural mucous membrane is destroyed, it is very common for nature to supply a new one. This is, of course, not always a disease;—any more than inflammation is always a disease. When a fistula takes place by the side of the rectum, or in the perinæum, it will acquire a lining membrane of a mucous character. Even in an old purulent cavity, a lining of this character is sometimes villi. When an abscess takes place in the lungs, and does not heal, but remains for a considerable length of time, the internal secreting surface acquires the character of a mucous membrane.

When a new mucous membrane is formed in the lungs, a cavity (constituting a vomica) will sometimes exist for years; and both the fistula and the cavity will be lined by something like mucous membrane. In all instances of this newly formed mucous membrane,—formed through disease, although by a restorative process,—it will be found to be one of the most simple character. A new mucous membrane so perfect as that of the intestines, however, is seldom seen;—it will never exhibit such villi. In its utmost state of advancement, it will be only like the mucous membrane of the urethra. The urethra presents one of the most simple specimens of a mucous membrane; while the mucous membrane of the intestines presents an example of a perfect description.

*Cutaneous Transformations.*—If a *mucous membrane* be exposed to the atmosphere, it acquires all the characters of *skin*. As already stated, skin and mucous membrane may be always classed together;<sup>b</sup> but if a mucous membrane be completely exposed to the air, so as to be dried, it becomes exactly like skin. We often have an opportunity of seeing this, in the instance of prolapsus of the womb. When the womb falls through the vagina beyond the external opening, and there remains (not being replaced by art), the vagina becomes dry, shrivelled, and pale,—like skin; and if it were allowed to remain there permanently, it would be difficult to tell the difference between it and skin. When the skin is destroyed, it may be reinstated by fresh skin.

*Fibrous Transformations.*—Conversion to *fibrous membrane* is very common; and it is the cellular membrane particularly, which undergoes this process. The cellular membrane will become indurated, so as to form cords; or so as to form a continuous membrane of a fibrous character; and frequently we have it indurated and accumulated into a mass. In all these cases, fibres may be seen; and in the midst of these fibrous bands may be observed cellular membrane, not yet perfectly changed. Tumours consisting of fibrous membrane, or of cellular membrane yet imperfectly converted into fibrous, may occur; they may be homogeneous, and may consist of lobes; or, again, of granules. Sometimes they will become vascular,—differing exactly as we see various *natural* fibrous membranes differ. They are more or less firm, according to the change which has taken place;—varying from the softness of pulp, to the hardness of bone. The structure surrounding one of these tumours, is often perfectly healthy; but sometimes it will be actively inflamed, and sometimes it will waste away. These tumours will occasionally take place after accidental inflammation; and sometimes they will occur without any obvious reason whatever. We sometimes see, that after the cellular has (in this way) been converted into a fibrous membrane, it becomes still harder; and forms cartilage, and even bone.

<sup>a</sup> Volume 15; Page 265.

<sup>b</sup> See Page 106.

*Cartilaginous Transformations.*—The transformation to *cartilage*, is also a very common morbid process; and takes place exactly in the same circumstances as the conversion to fibrous membrane. Very often it succeeds it, and is present with it. What becomes fibrous membrane at first, will often become cartilage afterwards. Cartilage, if of diseased origin, is very often formed of cellular membrane in the substance of organs; and frequently between the different tissues; so that it is common to see it under a serous membrane. When the pleura or the pericardium is observed cartilaginous or ossified, it is the cellular membrane immediately underneath the serous membrane, that is converted into bone. When cartilage is formed in this way, it is sometimes in mere little points, and sometimes in patches. This is a very common occurrence in arteries. Spots in the interior of an artery, of a different colour from the rest, excessively firm,—of a cartilaginous character, are sometimes seen; and these are formed under the lining membrane of the artery. Cartilage is frequently formed like a fibrous tumour,—in lumps or hard knobs. It is very common, after chronic inflammation of a serous membrane,—when the whole is thickened together,—to find a knob of cartilage here and there. Serous cysts frequently have knobs of cartilage in different parts; and frequently they are cartilaginous to a great extent. These knobs are found in the substance of different organs; but I believe they are for the most part cellular membrane, extending most frequently from the surface into the substance, and there increasing in size.

Cartilage, of new formation, is sometimes seen loose in the cavity. It is very common to see it in a joint; and it is not uncommon to see it in the veins of the pelvis. I believe it is formed under the synovial membrane, in the one case; and under the lining membrane, or inner coat of the vein, in the other. It protrudes, till at length it has a peduncle; which peduncle becomes thinner and thinner, till the whole is detached; and then we have a loose cartilage in the joint, or in the veins. I sent to the University<sup>a</sup> a specimen of the veins of the pelvis, in which were a great many cartilages, which could be moved about from one portion of the vein to another, like peas. Transformations to fibrous membrane and to cartilage, so frequently run into each other, that fibro-cartilaginous transformations result.

*Osseous Transformations.*—Induration, however, frequently proceeds farther than this. The natural *change of cartilage into bone*, is continually observed to take place in disease. After cartilaginous transformation has existed for a long time, we frequently find bone produced. It is said that the cellular membrane, fibrous membrane, and cartilage, are (strictly and positively) the only parts of the body that are ever converted into bone; but whether that is the case or not, they are the parts which by far the most *frequently* are so converted. The loose cartilages which I mentioned, as frequently existing in the veins of the pelvis, frequently become bone; so that we have hard bony substances loose in these veins; and these go by the name of “phlebolites,”—*vein-stones*.

When bone is deposited, the deposition may take place in the form of minute granules; so that the part is rough;—a condition in which the valves of the heart are frequently found. Or it may be deposited in the form of scales;—a character in which we frequently see it in the interior of arteries. When the radial artery is slit up, we frequently find bone deposited in minute scales, which may be removed from the interior; and sometimes it forms continuous plates. I have seen a kidney converted into a bony cyst, in which there was a *continuous* deposition of bone. This is a proper term; because the bone is deposited in a continuous manner, like membrane; but it would be wrong to say “*membranous*.” Sometimes it is deposited irregularly,—in an *amorphous*<sup>c</sup> manner.

It is sometimes deposited abundantly,—forming very considerable masses. We occasionally, in encysted tumours, find a piece of bone larger than a walnut; or perhaps as big as two walnuts. I have seen at least two or three instances of it. Bone thus deposited is sometimes homogeneous. If it be cut, it presents no fibres,

<sup>a</sup> University-College, London.

<sup>b</sup> From φλεψ, φλεβος, a vein; and λιθος, a stone.

<sup>c</sup> From α (privative) without; and μορφη, form.

and is without any reticulated portion. Sometimes it grows harder than natural bone. Sometimes it has rays or cross fibres, like diploe,<sup>a</sup> with an external compact substance. We see an instance of nature's highest efforts and powers in forming new bone, in necrosis; where a deposition, to a considerable extent, takes place under the periosteum; and which deposit will become a perfect bone, surrounding the old one. Diseased formations of bone are found to consist of phosphate and carbonate of lime, and of some animal matter;—just like healthy bone; but the proportion of phosphate and carbonate of lime is exceedingly various; so that we rarely find two cases of bone formed by disease, in which the proportion of the two is the same.

These are the chief observations which it was necessary to make on transformations. When structures are so converted, we say it is a *transformation*; and that it is into an *analogous* structure. That is to say, the structure which is produced, is analogous to a natural structure;—to a structure seen somewhere or other in the body during health. But besides these, we have *new formations*;—not *formations newly made* (that is not the meaning of the term); but *formations of a new character*;—something which is new to the body, and which is altogether of a diseased character. These are called “*non-analogous* or *heterologous* formations.”

## CHAPTER VIII.

### NEW FORMATIONS.

THE chief of these formations, of a solid kind, are *tubercles*,<sup>b</sup>—such as are seen in scrofulous cases; *melanosis*,<sup>c</sup> which is a formation of black substance; and sometimes a yellow substance, called *cirrhosis*.<sup>d</sup> Besides these, there are produced certain saline substances, unknown to the healthy body. For example: when speaking of calculi, we shall find a substance called “*xanthic oxide*,” and another called “*cystic oxide*,”—substances unknown to the healthy body. Some of the liquid products of inflammation (pus, for example) are unknown to the healthy body. The secretion of serum and of lymph, in inflammation, may be compared to analogous transformations. They are liquids subsisting in a healthy body; although their appearance in the part is unhealthy;—at least, their quantity is unhealthy. But we have a substance produced in inflammation, that is unlike the natural fluids of the body;—is a *new formation*, and of a liquid character;—namely, pus. There is an analogy running through all these things. In inflammation we have the liquid products of the part increased. For example: from a mucous membrane we have secreted more mucus than natural, and of an unhealthy quality; and from a serous membrane we have serum produced in abundance;—so that these may be compared to those changes of structure, in which there is merely an alteration of size and consistence, and in which the part becomes hardened or enlarged. Again: I mentioned that there are some diseases in which there is a *deficiency* of secretion;—as, for instance, “*ischuria renalis*,” and dryness of the skin; and these may be compared to softening and atrophy of substance, where there is a deficiency of matter. Then again we have, in inflammation, liquids secreted which are foreign to the part. For example: we frequently have lymph secreted; and though that is a fluid natural to the *body*, yet it is not natural to the *part*; and these secretions may be compared to those changes of structure, in which one part

<sup>a</sup> From διπλωα, to double.

<sup>b</sup> From “tuberculum,” the diminutive of “tuber,” a swelling.

<sup>c</sup> From μελας, μελανος, black.

<sup>d</sup> From κίττος, yellow.

<sup>e</sup> See Chapter 5; Page 175.

of the body assumes the character of another part; such as the transformation to cartilage or bone. Then, in inflammation, we have pus produced,—a new liquid; and (as I shall presently mention) in some diseases, a semi-fluid substance, like jelly; which substance is called “colloid,”<sup>a</sup>—from being like jelly. Sugar is sometimes formed in the urine; as well as the cystic and xanthic oxides, just alluded to. Cirrhosis, melanosis, tubercle, and encephaloid, are new solid formations. All these are called “non-analogous” or heterologous;”—being heterodox matters. Now some of these formations may be organized;—they are *organizable*, if such a word may be used. Scirrhus, for example, is of this description; fungus hæmatodes (as it is called), or encephaloid tumours, may also be organized; but tubercular substance cannot be organized. Scrofulous tubercles may become bone; but more frequently they are softened down, and pus is seen; but they are not substances capable of being organized, and forming part of the body.

## SECTION I.—TUBERCLES.

I shall begin the consideration of new formations with tubercles. The word “*tubercle*” has been employed in a vague sense. It is used by one person in one sense, and by another person in another; but there is now a great tendency to limit it to a scrofulous deposit. All small tumours in the substance of organs and serous membranes, or indeed upon the skin, have been called, and are still called “tubercles;” but the French have adopted the custom of restricting the word to tubercles of a scrofulous character; and it is in that sense that I now wish to speak of it.<sup>b</sup>

*Seat of Tuberculous Matter.*—[In whatever organ the formation of tuberculous matter takes place, the *mucous system*, if constituting a part of that organ, is, in general, either the exclusive seat of this morbid product, or is far more affected with it than any of the other systems or tissues of the same organ. Thus, the mucous system of the respiratory, digestive, biliary, urinary, and generative organs, is much more frequently the seat of tuberculous matter, than any other system or tissue which enters into the composition of these organs. The deposition of tuberculous matter on serous surfaces, is often observed; as in the cellular tissue generally, and on the free surface of serous membranes in particular. In those organs, into the composition of which the serous and mucous tissues enter, the tuberculous matter may be seen in both at the same time; as in the bronchi and air-cells, and in the interlobular cellular tissue; but in such cases it will be found to predominate in the former. And in those organs where there is no mucous tissue,—such as the brain, muscles, &c.;—we find the tuberculous matter deposited in the cellular tissue which unites their fibres or lamellæ. It very rarely occurs that tuberculous matter can be detected in the *blood*, while contained in its proper vessels. But it is frequently met with in this fluid in the cells of the spleen; the spongy structure of which admits of the accumulation of blood in such quantity, that the tuberculous matter can be seen forming in this fluid at some distance from the wall of the cells in which it is contained.

Repeated, careful, and minute anatomical researches, have led us to regard these, the mucous and serous surfaces and the blood, as the exclusive seat of tuberculous matter. In no instance is this morbid product deposited in the molecular structure of organs. It always makes its appearance on free surfaces, as a product of secretion. We must again repeat, however, that although it may form on serous surfaces, its *seat of election* is the *free surface of mucous membranes*. There, as into the great emunctory of the system, it appears to be separated from the blood, and becomes visible to us, under a variety of forms afterwards to be described. As a

<sup>a</sup> From *κόλλα*, *glue*.

<sup>b</sup> Tubercles, in all their varieties, form the subject of a paper (to which the reader is referred) in the thirty-eighth volume of the “Edinburgh Medical and Surgical Journal.”

morbid constituent of the blood, we can take no cognizance of the existence of tuberculous matter, otherwise than through the medium of the secretions, or until this fluid has ceased to circulate. Then it is seen to separate from the other constituents (the serum, fibrin, and colouring matter) of the blood; and is distinguished from them by the peculiarity of its physical characters.<sup>a</sup>]

*Form and Consistence of Tubercles.*—A scrofulous tubercle is of a yellowish white colour; and is usually round. It varies from the size of a millet-seed to that of a nut; and it is sometimes even still larger. It is firm, but friable; for although it is tolerably hard, yet if taken between the finger and thumb, it breaks down;—unless it have been converted into bone; and then, indeed, it is no longer a tubercle. Its character is curdy or cheesy; and it softens down into a substance, which is non-analogous to the rest of the body. It softens down into a sero-purulent fluid; but in this fluid we still have the friable tubercular substance, forming flakes within it. When the matter is let out altogether, a curdy substance floating in it is seen. When a tubercle softens down, the liquid (of course) has a tendency to escape, like the matter of an abscess. There is formed an abscess, which either increases or remains stationary for a time; and at length, when it is discharged, there is an attempt on the part of nature to heal up the part;—to produce cicatrization. These tubercles not being an organized substance, and not being organizable, must increase by juxtaposition;—exactly as stones would do, or any thing else inanimate.<sup>b</sup>

*Formation of Tubercle.*—It is supposed by some that a tubercle is liquid at first, and becomes harder afterwards. I should suppose that every thing in the body, when first secreted, must be liquid. One cannot conceive that vessels will pour forth solids. They all appear destined to hold liquids, however short a time the matter may remain fluid after its escape. It may, perhaps, become hardened immediately. Neither do I suppose that any thing can be absorbed but liquids. It is the opinion of Cruveilhier, that tubercles are liquid at first; and Andral likewise entertains the same opinion. Although they become of a yellowish white colour, yet they are at first grayish, and semi-transparent; and the semi-transparency gives a farther reason for supposing, that they are originally formed liquid. It is clear that they do undergo changes;—first having a transparency, and then becoming yellow; and we may suppose that there are more minute changes still; but changes which occur at too early a period, to render it possible for us to discern them.

*Softening of Tubercle.*—They soften down, it is said, by a deposition and secretion around them, penetrating and breaking them up. But I am not myself satisfied that this is a true account; because we often find them softened in the very centre, without any liquid which could have got into them. We find them firm externally, and liquid within, I should therefore suppose, that the softening of the tubercles was really a chemical change; and their not being organized forms an additional argument in favour of this opinion. If there be a deposition of external liquid matter, which goes into them, certainly the external part ought to be softened down as soon, at least, as the interior; but they generally soften at the centre. However, it is not invariably that they are softened down at the centre; for they will sometimes soften in other parts, especially upon the surface. When they are softened down, an abscess is formed, and the tubercular matter escapes. It is very common for fresh tubercular matter to be deposited within the cavity, after the discharge of the contents of the same character.

*Composition of Tubercle.*—When tubercles are not softened down,—when they are firm, they are found to consist chiefly of animal matter; with some muriate of soda, phosphate of lime, carbonate of lime, and traces of oxide of iron. This, how-

<sup>a</sup> Article "Tubercle," by Dr. Carswell, in the "Cyclopædia of Practical Medicine," Volume 4; Page 253.

<sup>b</sup> Dr. Carswell ("Cyclopædia of Practical Medicine") defines tuberculous matter to be "a pale yellow, or yellowish gray, opaque, unorganized substance; the form, consistence, and composition of which vary with the nature of the part in which it is formed, and the period at which it is examined."

ever, matters little. It is right to ascertain these points as far as possible, in the hope that it may lead to some important discovery hereafter; but still we do not yet understand their nature better, by understanding of what they consist. Some have an exceedingly firm cretaceous earthy matter. Of course, the same substances are found in all of them; but in proportion as they are firm, the phosphate and carbonate of lime abound, compared with the other materials. Dr. Carswell has made some beautiful drawings, representing tubercles in all their various stages; as well as numerous specimens of transformations and new formations;—such as ossification of the trachea, an ossified cyst, ossification of the valves of the heart, and an ovarian tumour containing bone; for teeth, and even hair, have sometimes been found in tumours of this description.<sup>a</sup>

*Organs liable to Tuberculous Deposit.*—“These tubercles are seen almost everywhere;—we find them in almost every part of the body; but they are more frequently met with in free cellular membrane, or in the cellular membrane which is a component part of different organs. Besides these situations they are found in the liver, in the brain, in the kidneys, in the testicles, and in the lymphatic glands. They are also found in the air-cells of the lungs, and in the parietes of these air-cells: and they are found also in the lymphatic vessels themselves.

[We have never found tuberculous matter in *cartilage, fibrous tissue, serous, synovial, or mucous membranes, tendon, or muscle*. When tuberculous matter has been found in the serous, synovial, and mucous membranes, the morbid condition of these membranes, which always accompanies the presence of tuberculous matter in them, has not been properly appreciated; for in such cases these membranes, particularly the mucous and synovial, are completely disorganized by inflammation; and converted into a reddish brown pulp. It is in this substance that the tuberculous matter is deposited; as may be ascertained by examining the mucous membrane of the intestines, and the synovial membrane of the knee joint, when in this state of disease.<sup>b</sup>]

*The Organs most usually affected at Different Ages.*—In adults tubercles are by far most frequently found in the lungs; and, next to the lungs, in the small intestines. In three hundred and fifty adults with tubercles in various other parts of the body than the lungs, Louis (the celebrated French pathologist) found only one whose lungs were free from them. When tubercles exist in adults, therefore, they are most frequently found in the lungs; and next to them come the small intestines. Speaking still of the adult, after the small intestines comes the mesentery, in point of frequency of this affection;—so that all other parts stand at a very great distance from the lungs, with regard to the frequency of tubercles in them. The intestines and mesenteric glands stand at a certain distance from the lungs, in point of liability to this disease; but all other parts stand even at a greater distance from them. So great is the tendency to them in the lungs, that Louis has made the calculation I have just stated. The liver is a part in which scrofulous tubercles are less frequently found than in any other; but they are by no means uncommon in the spleen, particularly in infants. In infants, it is very common for other organs than the lungs to contain tubercles, while the lungs remain free; which is just the reverse of what is observed in adults. In infants we more frequently find many organs affected at once than in the adult; in whom nothing is more common than to find them only in the lungs. In infants, too, the proportionate frequency of tubercles in different organs, is not the same as in adults. The frequency does not pursue the order of lungs, intestines, and mesentery; but follows quite a different rule. For example: they are far more frequent in the spleen, in the mesenteric glands (or, as they are called, the mesenteric ganglia), and in the bronchial ganglia. They more frequently affect those three parts, than the lungs; and they are much more frequently found in the nervous centres (the brain and the spinal marrow) of

<sup>a</sup> We must refer our readers to the splendid series of pathological plates which Dr. Carswell has published; entitled—“Illustrations of the Elementary Forms of Disease.”

<sup>b</sup> Article “Tubercle,” by Dr. Carswell; in the “Cyclopædia of Practical Medicine;” Volume 4; Page 259.

infants, than of adults. They are very rare, however, in the fœtus during its first months; but about the fourth year they become far more frequent; though they are not then very numerous. From the fourth to the fifth year, they are found to be very frequent; and attack many organs at once. So frequent are they in children at this period of life (at least in Paris), that Lombard says three-fourths of them perish from tubercular disease; or, at any rate, there is a tubercular deposit found somewhere or other, after death. After this age they become less frequent, till the period of puberty; though they are still more numerous than before the fourth year. From the fourth to the fifth year, as we have said, they are very frequent; then they decline for a time; but still they are more frequent than before the fourth year. It is found that children are more free from tubercles during the second year, than at any other period before the fifth. Tubercles are said to occur in men chiefly from the age of twenty-one to twenty-eight, and in women especially before the age of twenty. In men they appear later than they do in females.

*Not confined to Man.*—They are not confined to the human subject: they continually arise in brutes. I believe that, both in this country and at Paris, monkeys generally die of tubercular disease; and tubercles are found in a large number of their organs. They occur also in horses, pigs, cows, rabbits, hares, sheep, and birds. It is said that a great number of the parrots which die at Paris, have tubercles. Parrots, like monkeys, come from a warm climate; and become affected by the coldness and vicissitudes of such latitudes as Paris and our own. It is said,—but I do not pretend to know much of such matters,—that they are not found in dogs.

*Predisposing Causes.*—The predisposing cause of tubercles, certainly appears to be a want of proper food, and a want of proper external temperature. If an animal be kept in the dark, and likewise in a damp situation,—so that it is exposed to cold and damp, and particularly if it be fed on not very nutritious food,—we may, in many instances, produce tubercles at pleasure. I believe that the great and almost the only cause of tubercles, in the human subject, is the want of good food, and of a proper external temperature. Exposure to cold and moisture, and particularly (perhaps) *alternations* of temperature, will produce tubercles. When the disposition to them is once produced, it becomes hereditary; and children with every comfort around them,—well fed and well clothed,—are known to become, at a certain age, the victims of tubercular disease. The disposition, when once established, certainly becomes hereditary; but, without any hereditary predisposition, thousands and tens of thousands die of tubercular disease, from exposure to cold united with moisture, and the want of good food; and (in all probability), in a great measure, from vicissitudes of temperature. However, the influences of these causes may be much diminished by good food;—by keeping up a good fire within, we suffer much less from an external low temperature. It is food which is required for this purpose; not mere stimulants, such as spirits or wine. These will not answer the purpose. It must be good nourishment; which maintains a slow but constant fire (if I may so speak) within; and does not give merely a temporary excitement, which always increases the injurious effects of a subsequent low temperature. This subject, however, will be particularly spoken of when I come to the treatment of phthisis; which is the great tubercular disease of this country.

*Encysted Tubercle.*—This tubercular deposit acquires an enveloping membrane, and frequently two. Sometimes no lining membrane is discernible; sometimes the deposit takes place in a diffused manner, and it is then said to be “infiltrated;” but, in the lungs, the tubercular deposit is more frequently seen surrounded by a membrane, than otherwise. We may sometimes observe a capsule; in the interior of which we often find a softer membrane; which may be easily peeled off, while the external one is frequently pretty tough.<sup>a</sup> When it is formed, tubercular de-

<sup>a</sup> The term “*encysted*,” whether applied to pulmonary tubercle, or to tubercle in any other organ, is (according to Dr. Carswell) almost always incorrect. “In the lungs,” he says, “*encysted* tubercle is a deception;—the distended walls of the air-cells having, in all probability, been in almost every case taken for cysts. In like manner, the extremities of the

posit may remain for years without injury; but if the deposition be very great, it forms a source of irritation. If a great quantity be deposited in different parts,—and often, indeed, where the deposit is trifling,—the surrounding substance falls into a state of irritation; the tubercular substance softens; and that process takes place which I have already mentioned.<sup>a</sup>

*Appearance of the Ulcerating Cavity.*—The cavity, when the matter is discharged, is for the most part irregular. It is not of a definite shape, but irregular. Its parietes generally grow harder and harder; and frequently the tubercular substance is not entirely discharged, but adheres pretty firmly to the sides. These cavities frequently have sinuses communicating with the external surface, or with the large bronchial tubes. When the tubercle has been near the surface, (which is very common in the case of the absorbent glands,) the ulcer has generally a flabby edge, which is turned inwards;—the very reverse of what takes place when an ulcer is cancerous; and it often heals up perfectly well. Even in the case of the lungs, we shall see that occasionally such cavities do certainly heal.

*Character of the Pain.*—These tubercles are attended by no pain, so far as the deposition itself is concerned; but the irritation around is frequently a cause of pain; and if a tubercle be near the surface of the lungs, the pleura generally falls into a state of inflammation. There is more or less pleuritis; and the person suffers pain in the side. When a tubercle is producing much inflammation around, of course there must be the usual signs of inflammation. In the case of the glands of the neck, there is considerable pain when active inflammation is excited.

*Scrofulous Diathesis.*—The disposition to form these tubercles, is called “a scrofulous habit of body;” and the person is said to labour under scrofula (or struma) when labouring under such deposits as these. The marks of a constitution so disposed are, generally, a fair and fine skin, fine soft hair, a dilated pupil, and a large upper lip; and it is observed, that when the internal parts labour under scrofula,—not the external parts, but the internal viscera,—the extremities of the fingers and thumbs, and even of the toes, become enlarged. It is a remarkable circumstance; but it happens in a great number of cases of phthisis, and certainly in scrofula of many other parts,—such as the liver, and the mesenteric and lymphatic glands,—that the ends of the fingers become enlarged. I presume that a faint scrofulous inflammation attacks the last joint. Many persons, however, are scrofulous, who have neither a fair skin nor soft hair; but, on the contrary, a dark complexion. But still they look pale, and have dilated pupils and a tumid lip; and perhaps are pock-marked. Those more particularly disposed to it, however, certainly have a fair skin, a pulse disposed to be quick, and elongated fingers. When the disease, however, becomes established,—when tubercular matter is deposited, the ends of the fingers enlarge; so that the nail is prominent. It is like an acorn,—exceedingly convex; and the last joint altogether becomes broad.

This disease, as I said,<sup>b</sup> may undoubtedly be hereditary; and is so in a very large number of cases. It is a disease that attacks persons of all ages; but particularly in the early parts of life; while the disease of which I am now going to speak, is rarely seen in the young,—rarely seen before the middle period of life; and generally not until after the middle period is past.

biliary ducts, when dilated, and filled with tuberculous matter, have been described as encysted tubercles; and we have already said that the dilated air-cells, particularly in the cow,—which may vary from the size of a pea to that of a cherry,—have frequently been regarded as hydatids. We do, however, meet with encysted tuberculous matter; but not until it has undergone important changes, which precede its ultimate removal from the organ in which it was formed.” (“Cyclopædia of Practical Medicine,” Article “Tubercle;” Volume 4; Page 253.)

## SECTION II.—CARCINOMA.

*Definition.*—[Those growths may be termed “cancerous,” which destroy the natural structure of all tissues; which are constitutional from their very commencement, or become so in the natural process of their development; and which, when once they have infected the constitution, if extirpated, invariably return, and conduct the persons who are affected by them to inevitable destruction. The forms of disease which may be classed under this head, are extremely various; though, in some cases, they pass into each other by imperceptible gradations. This fact, and the circumstance that, after extirpation of the disease, one form may take the place of another, serve to exhibit the physiological connection between growths, the extremes of which often do not show even the most remote similarity of structure. After extirpation of common cancer of the mammary gland, “*fungus medullaris*” may form, either in the breast or in some internal organ. “*Carcinoma simplex*” and “*alveolare*” are sometimes met with together in the mammary gland; and “*carcinoma reticulare*” and “*melanodes*” in the orbit. “*Carcinoma fasciculatum*,” altogether fibrous in structure, and destitute of even the most remote resemblance either to “*fungus medullaris*” or to common cancer, exactly resembles them in physiological characters.

*Minute Structure of Carcinoma.*—The most invariable anatomical character of the carcinomatous degeneration, is loss of the proper tissue of the affected part; which always disappears during the progress of cancer. Vessels, muscles, nerves, glands, bones, and all other tissues, how different soever from each other, become alike involved in the same cancerous degeneration. The first appearance of cancerous degeneration, however, does not consist in the mere transformation of the previously healthy tissues; but the elementary forms of carcinoma become developed between their interstices, and thus displace the natural structure. That this is the case, is shown by the way in which the elementary forms of carcinoma are produced. It can easily be proved, that the germinal cells of carcinoma are formed, not from any previously existing fibres, but from a real *seminium morbi*; which develops itself between the tissues of the affected organ. This is best displayed in the alterations which the muscular coat of the stomach undergoes from “*carcinoma alveolare*.” The germinal cells of carcinoma, are deposited between the bundles of muscular fibre; which, in the early stages of the disease, are easily distinguishable: at even a later period the muscular layer of the stomach, though enormously swollen, may still be recognised; until, at length, the production of the germinal cells, equally in all the coats of the stomach, obliterates every trace of their different layers, and of the natural structure of the organ.

The parts in the neighbourhood of a cancer, usually become firmly connected with it at an early period: hence carcinoma is less movable than other growths. Carcinoma of the stomach adheres to the pancreas, or the liver, that of the female breast to the skin, or the pectoral muscles. In the female breast, the condition of the nipple and its early retraction are characteristic; though neither that, nor the connection of the scirrhous growth of the pectoral muscles, is invariably met with. Indeed, the author<sup>a</sup> has often observed carcinomatous growths, in which neither of these occurrences had taken place. The retraction of the nipple, in cancer of the mammary gland, depends on its proximity to the disease. The swelling of the axillary glands, in carcinoma of the breast, and the existence of similar swellings in other neighbouring parts, are both important. The dilatation of the veins, however, cannot be depended on as a sign of malignancy.

*Presence of Septa.*—In cancer of the stomach, the condition of the muscular coat affords a sure anatomical sign of carcinoma, whatever may be its form. In most cases of carcinomatous disease of the walls of the stomach, the muscular coat not merely becomes exceedingly swollen, but its section presents a partitioned

<sup>a</sup> Müller.

appearance; which is partly the result of the bundles of muscular fibre having been divided, but in part also is caused by the division of membranous and fibrous septa and capsules. In the intervals of the bundles of muscular fibre there become developed, in some parts, the cellular globules of "carcinoma simplex," and the cells of "carcinoma alveolare;" in other situations, fibrous septa run in different directions. Often, on closely inspecting the surfaces of these sections, membrano-fibrous septa are seen running between the interstices of the muscular bundles, and crossing each other irregularly. These compartments are filled with gelatiniform cells, which enclose smaller cellules; so that the interior of the capsules themselves seems to be subdivided. On a few occasions, the author<sup>a</sup> saw similar capsules apparently filled with fibrous masses. The septate appearance of the muscular coat, shows itself at the very commencement of cancerous degeneration: in "carcinoma alveolare" it may subsequently disappear, when all distinction of tissues in the different layers of the stomach has been completely confounded;—having given place to the cells filled with a gelatiniform substance. Engravings of this appearance of the muscular coat of the stomach, are to be met with in most illustrated works on pathological anatomy; in which the structure of cancer of the stomach, as far as it is visible to the naked eye, is represented.<sup>b</sup>

This septate character is not peculiar to the muscular coat of the cancerous stomach; it is also observed in other muscular parts, when affected by carcinoma. In Pockel's museum, at Brunswick, the author<sup>a</sup> noticed this appearance in a specimen of scirrhus of the rectum; and in another of scirrhus of the œsophagus, complicated with scirrhus of the stomach. It occurs also in the urinary bladder.<sup>c</sup>

This appearance is not characteristic of any peculiar form of cancer, having been observed in most of its varieties;—in "cancer alveolaris," in "carcinoma simplex," and medullary sarcoma of the stomach.

There are no other general characters of carcinoma. Eccentric development is not peculiar to it; neither does softening always begin at the centre of the growth; nor is it always characterized, in its early stages, either by a lack of vessels, or by any peculiar distribution of them. The vessels in it bear the same relations as in other parts. Sometimes they are scanty; at other times exceedingly numerous.

*It is not Heterologous.*—The positive characters of carcinoma do not display any thing heterologous or foreign to healthy organization.<sup>d</sup> Some of the elements of cancer occur in the healthy organism of the adult, while others are such as exist in the primitive fœtal state of tissues; as cells, varicose fibres, and cylindrical fibres. Varicose fibres are produced by the elongation of cells, and their linear arrangement; and perfect fibres are, in their turn, formed from such as are in the varicose state; whence it follows, that the differences of the extremes depend merely on the point at which the development of the tissues is arrested. A structure, the development of which is arrested while the cells are in their primary state, will be very unlike one in which the cells are elongated, and in progress of

<sup>a</sup> Müller.

<sup>b</sup> See Cruveilhier, "Anatomie Pathologique," Livre 12, Planche 6; Carswell, "Pathological Anatomy," "Carcinoma," Plate 1, Figures 1 and 2, and Plate 3, Figure 1; Seymour, "Medico-Chirurgical Transactions," Volume 14, Plate 1; Baillie, "A Series of Engravings," &c., Fasciculus 3, Plate 7, Figure 1.

<sup>c</sup> In Baillie's "Morbid Anatomy" (Fasciculus 3, Plate 4, Figure 2), is an engraving of the septate structure of carcinoma of the œsophagus; and another of carcinoma of the rectum (Fasciculus 4, Plate 4, Figure 1).

<sup>d</sup> The greater number of modern pathologists, regard these various structures as non-analogous, or heterologous formations. So great an authority as Müller, however, contends,—on the grounds of chemical analysis, and microscopic investigation,—that they are essentially analogous formations. Schleiden has also subsequently shown an intimate similarity between the ultimate cells of cancerous structures, and the primitive formations of embryo-life. But the question of importance (in reference to this reputed analogy) which presents itself to me, is not whether the elementary components may not be the same, but whether the same elements appear in similar combinations in natural structures. The negative of this is on the side of probability. Cancer, therefore, in all its varied phases, is a tissue which has no counterpart in the normal structures of the living body.—T. Williams.

transformation into fibres; while those growths which tend rapidly to assume a fibrous texture, will also present a different appearance.

*Principally formed of Albumen.*—An albuminous substance forms the basis of all carcinomatous growths; for, if freed from skin and cellular tissue, they may be boiled for eighteen or twenty-four hours, without yielding more than a very small quantity of gelatine; often, indeed, without the slightest trace of it being discovered. What little of it is dissolved occasionally, contains caseine and salivary matter.<sup>a</sup>

### a. Scirrhus, or Carcinoma Simplex.

*Formation.*—It appears that there are two changes in scirrhus;—there is a *transformation* and a *new formation*. It would appear that the cellular membrane of the affected parts becomes exceedingly indurated, and is changed into a hard fibrous membrane; but in the midst of this there certainly is a new deposit, of a particular description.

*Structure.*—When scirrhus takes place, we see a firm, exceedingly hard, unequal, irregular mass. It is of a light grayish colour at first; and, if cut into thin slices, is semi-transparent. If a section be examined, a large number of fibres traversing morbid structure in different directions may be seen, between which fibres there is a substance less white than the rest. The deposition constituting tubercles is organic; it is not a new *organization*, but a new *deposition*. In scirrhus there is a transformed structure, at any rate; and besides that, there is an inorganic substance, deposited between the fibrous portions. These fibrous portions, running in different directions, form septa,—divisions; and are opaque and paler than the others; that is to say, of a more dead white. In fact, the section of a scirrhus tumour is exactly like that of a turnip. In a turnip, we observe fibrous septa, running in different

<sup>a</sup> "The Nature and Structural Characteristics of Cancer," by J. Müller, M.D. Translated by C. West, M.D. 1840. Pages 28 to 32.

directions; and a softer less white substance between them. The septa, in scirrhus, run in every direction; and sometimes are seen to form regular cells. The proportion of less hard substance between the fibres, is exceedingly various; and the mode in which the fibres are distributed, is likewise exceedingly various; so that sometimes we have a mammary tumour, sometimes a pancreatic tumour, and sometimes a tubercle;—that is to say, a tumour something like a mamma, or something like a pancreas, or something like the tumour of scrofula;—a tubercle, in the common acceptance of the word, may occur.

*Microscopical Characters.*—[The diseased masses are generally irregular in form; not lobulated; hard, and resisting the knife; and presenting, when divided, a grayish appearance, which has but very little similarity to cartilage. Whitish bands are not invariably present. Scirrhus of the mammary gland occasionally shows, here and there, whitish filaments; some of which are hollow, and contain a colourless, whitish, or yellowish matter. Probably this appearance of white filaments, is the result of thickening of the walls of the lactiferous tubes and lymphatics; and this idea is confirmed by the absence of these filaments from scirrhus of non-glandular parts. The mass of scirrhus is composed of two substances; the one fibrous, the other gray and granular. The fibrous substance is rarely apparent immediately on making a section of these growths; but is seen on scraping away the gray matter, for which it serves as a sort of basis. On removing the gray matter, either by scraping it away or by maceration, the fibrous substratum is seen to be composed of a very irregular network of firm bundles of fibres. The gray matter is found to consist of microscopic, formative globules, but slightly adherent to each other, and varying from 0.00048 to 0.00108 or 0.00130 of an English inch in diameter. They are insoluble in acetic acid, and also in water, at any temperature. In many of these cells, only a few points, which look like small granules, can be seen; while in others may be distinguished a larger body, which looks like a nucleus, or like a smaller vesicle, contained within a formative globule. Though crowded closely together, the formative globules lie between the meshes of a fibrous structure, with which they have no connection, and from which they can be easily removed; while, notwithstanding the thinness of their walls, they can be isolated from each other with the greatest facility. It is difficult to make out whether the single or double vesicular corpuscule, which is often distinctly seen within the formative globule, corresponds to the nucleus of a cell, or whether it is a young cell encased within the old one. If it be a nucleus, then the small spot upon it would be analogous to the nucleolus, which Schwann usually found on the nucleus of the cells in the fœtus. If, on the other hand, the pale (apparently vesicular) corpuscules be in reality young cellules, then the corpuscules on their surface would correspond to the parietal nucleus from which other cells are developed. The paleness and transparency of the vesicular corpuscule which may be contained within the formative globule, does not by any means prove it not to be a nucleus; for, in the fœtal tissues, the nuclei are sometimes remarkably pale, and even present a vesicular appearance. Probably, however, the vesicular bodies do correspond to young cells; and the analogy of this structure to that of “cancer alveolaris” is greatly in favour of this supposition. In a case of “carcinoma mammæ,” which occurred in a woman aged fifty, the same structure which was observed in the breast, and which there appeared to contain young cellules, showed itself also in small tumours of the ribs. Since many structures in the embryo are originally developed from cells, there exists a general resemblance between the cellular texture of carcinoma, and the primitive state of those tissues. But this is merely a general analogy; for the structure of carcinoma does not resemble one tissue more than another. Professor Valentin,<sup>a</sup> indeed, has observed bodies with central nuclei,—which he considered to be cartilage corpuscules somewhat altered,—in the sanies from a carcinomatous sore of the face, as well as in the substance of the diseased mass itself. It is uncertain, however, whether these bodies were

<sup>a</sup> Repertorium für Anatomie und Physiologie, 1837. 2 Abath. p. 263, 292.

real cartilage corpuscles, or whether they might not have been cells of the kind just mentioned. In addition to the formative globules of carcinoma, oil-globules are always seen, in considerable number, diffused through scirrhus growths.\*]

*Softening of Scirrhus.*—The less hard substance, at last, undergoes the same process as a true scrofulous tubercle. It softens down into an ichorous fluid,—into something like jelly or gum; and the process here begins usually,—perhaps always, but at any rate usually,—in the centre; as is generally the case in scrofulous tubercles;—the centre having been originally the hardest part.<sup>b</sup> The skin above becomes puckered, or retracted; and its colour also becomes changed. It assumes a leaden, or livid hue. At first, the whole tumour is movable; though it will not allow the whole of the fingers to be placed under it;—it will not allow the edge to be turned up. But, after a time, it forms adhesions to the neighbouring parts, and becomes immovable.

*Ulceration.*—Ulceration takes place in a scirrhus mass, exactly as in the case of a scrofulous tubercle; and when the ulceration begins, that state of things is called “cancer;”—scirrhus being the first stage (the stage of induration); and cancer the second stage (the stage of softening and ulceration). In this form of ulcer, the edges are everted and elevated;—we see the edges much raised, irregular, and turned out. The surrounding cellular membrane undergoes the process of suppuration. Now and then we see a sort of fungus sprouting up from the ulcer;—a hard gristly fungus. The centre of such an ulcer is deep; the discharge is generally very fetid; and great irritation is produced. Sometimes, instead of a simple suppuration around, we have sloughing, and now and then nature succeeds in throwing off the whole mass;—the scirrhus tumour has not formed adhesions to the surrounding parts; but suppurates, or rather sloughs out. The lymphatic glands, to which the absorbents of such a tumour run, generally become contaminated. They generally become indurated,—scirrhus; and undergo the very same process as the original part.

*Character of the Discharge.*—[The liquid ichor, or sanies, which forms the discharge from cancerous sores, is thin, acrid, and generally of a dirty green colour; but liable to variation in tint from admixture, in various proportions, with effused blood, or from impregnation with melanotic fluid; as in a case related by Rouzet. It possesses a peculiar, and almost characteristic factor. It is said by some to effervesce with acids, and turn syrup of violets green; but Ploucquet found, on the contrary, that it exhibited the reactions of an acid. In warm countries, especially, generation of worms not unfrequently occurs in this matter.<sup>c</sup> There is nothing, however, peculiar to the cancerous discharge in such development; yet the fact seems to have led to the singular theory respecting the production of cancer by an insect. Valentin states his having discovered nuclear globules, and cartilage-corpuscles in the “pus of a cancer;” but, according to Müller, such discharge is not peculiar to this affection;—occurring, on the contrary, from all suppurating surfaces. To the similitude of pus granules, and nuclear epithelium cells, we have already adverted. The surface of the ulcer may participate in the kind of formation displayed by the whole mass: thus, Müller has seen the white net-work of reticular carcinoma spreading into the minute asperities on the surface of fungating growths. In encephaloid, consisting of caudate corpuscles, the tailed appearance is found in course of development in the most superficial part of new vegetations. The same observer once saw a thick layer of polyhedral chole-steatomatous non-nuclear cells, forming a mass like tallow, on the surface of a cancerous ulcer in the mamma.

*Sometimes Cicatrize.*—Singularity as the fact clashes with the general laws of

\* Müller, on “Cancer;” Pages 41 to 44.

<sup>b</sup> The process of softening may commence in any part of a carcinomatous tumour;—as well at the periphery as the centre. The notion of the constancy of central softening, has been shown to be incorrect by careful observation. The change may originate in a single spot, or simultaneously in several.—“*Cyclopædia of Practical Surgery;*”—Article “Cancer;” Volume 1; Page 617.

<sup>c</sup> Vacher; “Dissertation sur le Cancer des Mammelles;” Page 81.

carcinomatous growths, it is no less true, that these products are not wholly incapable of *cicatrizatio*n. Scirrhus ulcers occasionally assume a healthy vermilion tint, become covered with normal granulations, and actually cicatrize over a greater or less extent of surface. Abernethy relates a case of encephaloid tumour of the groin, in which, after the removal of a "portion of the tumour," the ulcer gradually "lost its inflamed aspect, granulations formed, and a cicatrix took place." M. Berard witnessed a similar occurrence; and cerebri-form cancer of the limbs and meninges, has been known to cicatrize in the same manner, after inopportune incision. According to Bayle, the majority of scirrhus formations in which this change is observed, are of a particular structure and character. Pouteau considered them the most intractable of all. Certain it is, that the amendment is delusive and temporary: the process ceases; and the disease advances with renewed activity. It must be understood, that we here refer solely to cicatrization occurring over actual cancerous substance.

The reappearance of carcinoma in the situation of its previous development, after the spontaneous separation, or artificial removal of a tumour, is unfortunately a most common occurrence. This *local reproduction* is effected in different ways:—1. The process of cicatrization may not distinctly commence, or may be interrupted at an early stage; and fungating growths may spring from some part of the wound. 2. A perfect cicatrix forms; and, after a variable lapse of time, a tumour grows in the subjacent tissues; presses on the inodular structure; destroys it; appears externally; and, on examination, presents the characters of carcinoma. 3. Reproduction may be accomplished in the tissue of the cicatrix itself, by the development of tuberiform, or infiltrated carcinoma.

To whichever species the original growth may belong, the secondary formation is ordinarily encephaloid; whence, probably, the observation that consecutive, run their courses more rapidly than primary, tumours.<sup>a</sup>]

*Parts liable to Scirrhus.*—This is a disease which in general primarily affects those parts which are not necessary to life. It affects glands the functions of which have been interrupted, or have never been performed; it affects the breasts,—particularly when a woman is past child-bearing; and it particularly affects the breasts of women who have never had any children. It also, where there is any predisposition, particularly affects parts which have suffered mechanical injury. Many women have had cancer in the breast after a blow; though, in all probability, they would not otherwise have suffered. It particularly affects the breast, the uterus, the ovaria, the testes, and the thyroid gland; none of which parts are necessary to life;—the breast, uterus, ovaria, and testes, being all for the sake of the next generation, and not for the sake of ourselves;—except, indeed, as a gratification. The thyroid gland is, of course, a part unnecessary to life.

*Parts secondarily affected.*—When, however, cancer has existed in these parts, it affects others secondarily; and then we find the lungs, liver, omentum, mesentery, spleen, pancreas, brain, the medulla of the bones, and the skin, become the subjects of the affection. Now and then it may affect these parts primarily; but as a general rule,—and one can only speak generally,—it affects the parts which I have last mentioned only secondarily. When it affects the skin primarily,—which it now and then does,—a kind of wart is the first thing which appears; and it becomes cancerous. If it affect the skin only secondarily, then (I believe) more generally we have a tubercle, in the common sense of the word;—a little hard lump. When the breast has been affected with cancer, the skin in the neighbourhood will become the subject of *tubera*;—little hard scirrhus lumps. We certainly often see cancer affect the cardia, the pylorus, and the rectum primarily; yet although it sometimes does so, it is by no means so frequent an occurrence, as the affection of those particular organs which are not necessary to life, and the functions of which may cease without the body at large suffering. When it affects the alimentary canal, it attacks particularly certain portions, which form divisions of it.

<sup>a</sup> "Cyclopædia of Practical Surgery;" Article "Cancer;" Volume I; Pages 617 and 618.

For example: it affects the lips, which are the first part; next to them it will affect the fauces, and the cardia;—the lips forming the commencement of the mouth, the fauces of the throat, and the cardia of the stomach. Then it affects the pylorus, —the commencement of the intestines; and then, again, it affects the rectum; which is the termination of the canal. It is a curious fact, that it is generally the *apertures of cavities* that are affected. We shall see, when we come to consider diseases of the heart, that it is the openings which suffer, far more than any other portion of that organ.

*Effects on the adjoining Parts.*—In certain situations, cancerous deposits may acquire considerable volume, without apparently influencing the substance of the part in which they are formed; but, in other situations, the presence of carcinoma leads to certain changes in the surrounding tissues. They may be stated briefly, thus:—1. Condensation. 2. Obstruction of function, from mechanical pressure. 3. Discoloration of the surrounding parts. 4. Hypertrophy, or atrophy. When carcinoma is so situated as to obstruct the functions of some of the hollow viscera, hypertrophy of the muscular apparatus behind the obstruction is the result; as in disease of the cardia or rectum. But in scirrhus of the mamma, there is frequently hypertrophy of the glandular structure; so that it scarcely, if at all, exceeds its healthy fellow in size; while, in other cases, its general bulk may be increased, or parts of it may be tumefied, and others atrophied. 5. Absorption of the neighbouring parts. 6. Serous infiltration. 7. Inflammation, either eliminatory in its effects, or not. 8. Fibrous transformation. 9. Extension of the disease to contiguous textures, by infiltration.

Such are the changes produced on the adjacent tissues during the progress of carcinoma; but the carcinomatous tissue itself, being (like normal textures) the seat of nutrition, is (like them) susceptible of its disordered actions. Of these, the principal is congestion;—arising either from irritation of the arteries, or obstruction of the veins. The first consequence, as may be supposed, is a change in the colour of the diseased mass; which may either assume a florid hue, or a purple, brown, or black tint,—according to the cause of the obstruction; but—owing to the delicacy of the vessels in the adventitious growth, the trifling support received from the substance in which they ramify, and their imperfect communication with each other—extravasation of blood almost always follows;—frequently causing a sudden increase of the non-ulcerated tumour. The subsequent changes of the effused blood, are strikingly similar to those observed in cerebral hæmorrhage. The liquid portion is gradually absorbed, with the hæmatosine; the discoloured fibrin remains behind, in a sort of cavity lined with a smooth and delicate membrane; while the circumjacent cancerous matter acquires a yellow tint. At a more advanced period, the clot disappears; the lining of the cavity is more distinctly serous in its character; and its contents are of a serous, or glutinous nature. Such is, doubtless, the origin of the greater part of the cysts found in the interior of carcinoma.\*]

*Attendant Symptoms.*—The disease is attended, in general,—almost from the very earliest stage,—with severe pain;—sharp, lancinating, and of the most dreadful kind. The pain certainly does not depend upon inflammation; for it will occur where no inflammation can be discovered.

[*Hæmorrhage.*—Hæmorrhage, which does not ordinarily occur before ulceration has set in, is sometimes one of the earliest effects of the disease. Thus, the discharge of a few drops of blood from the nipple, in scirrhus of the breast,—a tolerably frequent occurrence,—has, in some rare instances, been the first morbid phenomenon observed. Profuse menorrhagia, in not a few cases, precedes all other

\* "Cyclopædia of Practical Surgery," Article "Cancer," by Dr. Walshe; Volume 1; Page 612.

<sup>b</sup> Scirrhus formations, in their early stage, are not endowed with any marked *sensibility*. It has been remarked, however, by numerous observers, that pain is very commonly experienced about half an hour after these tumours have been examined. When pain is excited immediately after or during pressure, this, according to some writers, is owing to the presence of inflammatory action in the tissue surrounding the cancerous substance.—"Cyclopædia of Practical Surgery," Article "Cancer," Volume 1; Page 634.

symptoms of uterine cancer; and in a case of pharyngeal carcinoma, which we observed some years past, the patient persisted in affirming, that severe hæmorrhage from the throat was the first circumstance that drew his attention to the part. In a similar manner, hæmoptysis is frequently the first occurrence announcing tuberculous disorganization of the lungs. But we would not be understood to mean, that effusion of blood is really the very first abnormal effect of the heterologous formation: others have probably led the way; but, from their trivial character, escaped the attention of individuals who are not in the habit of carefully watching the variations of their health. Admitting this to be the fact, the practical value of hæmorrhage, as a symptom, is by no means lessened.

*Derangement of Function.*—Derangements of function form an important item in the symptomatology of carcinoma; and, of course, vary with the organ in which, or in the immediate vicinity of which, the morbid matter is developed. They may be included under the heads of “irritative” and “mechanical.” As illustrations of the former, we may adduce the vaginal discharge produced by non-ulcerated scirrhus of the uterus; and the occurrence of hydrothorax and pleuritis, in subjects affected with mammary cancer. In exemplification of the latter, may be mentioned the occurrence of amaurosis, from pressure on the optic nerve; the interruption to vision, occasioned by tumours driving the eye from its normal site; obstinate constipation, from pressure of enlarged pelvic glands; derangement of local circulation and serous accumulation, either in the shut cavities or in the cellular membrane, produced by partial closure of adjacent circulating tubes,—arterial, venous, or lymphatic.\*]

*Sloughing Stage of Cancer.*—When the stage of ulceration has arrived—in which there is inflammation, sloughing, and suppuration,—the irritation is so great, that the whole constitution suffers materially; and the skin acquires a peculiar sallow tint;—a sort of pallid yellowish straw-colour. The state of the body is decidedly cachectic; that is, the whole body is in an unhealthy state. Andral ascribes this sallow appearance to a change which the blood undergoes;—the constituents of the vital fluid being absolutely altered. There is a sallow look; by which any experienced person will suspect, that the individual is labouring under some malignant disease. This has been called “cancerous cachexia;”—“*cachexia*” meaning a bad habit of the whole body.

[To this catalogue of evils may be added, as of not very uncommon occurrence, a morbid change of the bones, exhibiting itself in some one of the following forms:—1. Atrophy of the spongy and compact structures, from defective nutrition. 2. Excess of inorganic matter in their composition. 3. Defective supply of saline materials; in consequence of which, the bony tissue appears as if it had been macerated in a mineral acid (“*carnification*.”) 4. Carcinoma of their substance. The first of these forms is singularly rare. Recamier, however, appears to have met with an example of it. Of the third we have not met with an authentic instance; and insert it rather hesitatingly. In the first three cases, the morbid state is a manifestation of the *cachexia*; in the fourth, it is an evidence of the diathesis having reached the bones. In the first, second, and fourth cases;—especially the last,—fractures occur with extraordinary facility. In cases of cancerous deposition in the bones, the fracture may either arise from complete transformation of a portion of the cylinder into cancerous matter, or from the pressure of a central growth;—causing the absorption of the compact tissue. When the fracture is of the former description, crepitation will either be wholly absent or ill-marked; in the latter case, this sign is producible in the ordinary way. When a cancerous patient suffers persistently, or pretty constantly, from pain in a particular spot in the course of a bone, the occurrence of such fracture is to be apprehended; but such local pain is not a constant forerunner of the accident, nor is it necessarily followed by it. The pain has been mistaken by patients for rheumatism; and this error has, not unfre-

\* “Cyclopædia of Practical Surgery,” Article “Cancer,” by Dr. Walshe; Volume I; Page 635.

quently, been shared by the medical attendant.<sup>a</sup> In not a few cases, the occurrence of fracture has manifestly hastened the fatal issue of the disease.<sup>b]</sup>

*Termination of Scirrhus.*—I mentioned<sup>c</sup> that the diseased part sometimes sloughs out; and the person recovers. That, however, is so rare a circumstance, that even if the surgeon remove the disease, the relief is but too often temporary; for, in the greater number of cases, the disease reappears;—either in the same neighbourhood, or in an opposite part. It would appear that it depends, in a great number of cases, upon some constitutional tendency; and all that art can do is to remove those parts which have fallen into a diseased state; but, as the tendency remains in the constitution, persons generally show the disease again, sooner or later, in some other situation, or around the spot of the operation.

*Hereditary Predisposition.*—This disease, like scrofula, may be hereditary;—I mean, of course, the disposition to it; and it is not known (at least, as far as I am aware) what circumstances give a predisposition to it. Those which give a predisposition to scrofula, are evident enough; but I am not aware of any circumstances, which are known to give a predisposition to scirrhus and cancer. I have known many persons die of cancerous disease, one of whose parents had previously died of the same affection. There are several drawings by Cruveilhier, illustrating the various stages of this affection.<sup>d</sup>

### b. *Encephaloid Disease.*

*Its Nature.*—The next disease of which I shall speak, is one which differs from scirrhus and cancer, in affecting the young rather than the old. It is what is called “fungus hæmatodes,” or “encephaloid disease.” It has been called “encephaloid,” because the deposition is not hard, like scirrhus; but, to a certain extent, resembles the brain. It has also been called “fungus hæmatodes;” because, when it arrives at the stage of ulceration, a fungus, of a bloody character, sprouts out; and, on cutting into it, we see large distinct cells filled with effused blood. It is, therefore, like brain in some parts, and is bloody in others. The deposited matter is like brain; but in the cells in which the deposition takes place, hæmorrhage continually occurs; so that blood is effused there, and a coagulum forms. There is a great disposition to hæmorrhage in this disease; but the deposit itself is an opaque, whitish, homogeneous substance; and may be compared, in colour and consistency, to cerebral pulp. There is an excellent representation of the affection, by Dr. Carswell; taken from cases in which it was situated in the brain and liver. I have opened many brains and livers, containing tumours about the size of a walnut; which, on being cut into, presented a homogeneous brain-looking pulp. There is often nothing like the firm fibres of scirrhus;—no distinct white bands ramifying in the tumour; but a mass such as I have just described. When exposed to the air, it softens down,—just as the brain will do; and it may be washed away,—leaving a filamentous texture. If a tumour of this description be taken, and exposed to a stream of water, the pulp may be washed away; leaving an exceedingly fine filamentous structure, which has contained the opaque brain-looking substance; but then this structure, unlike scirrhus, is exceedingly fine and delicate. The consistency of encephaloid substance varies;—from that of a soft custard, down to the firmest part of the brain when perfectly fresh. One portion of this is sometimes pinkish; and sometimes portions will be as red as a clot of blood; but if the blood have been effused in great quantity, regular clots of blood appear. Various portions differing in colour, size, and consistency, are often found; and some of them are

<sup>a</sup> Salter, in the “Medico-Chirurgical Transactions;” Volume 15; Page 186. Samuel Cooper, in the same; Volume 17; Page 51.

<sup>b</sup> “Cyclopædia of Practical Surgery;” Article “Cancer,” by Dr. Walshe; Volume 1; Pages 636 and 637.

<sup>c</sup> See Page 199.

<sup>d</sup> “Anatomie Pathologique du Corps Humain; ou Descriptions, avec Figures Coloriées et Lithographiées, des diverses Alterations Morbides dont le Corps Humain est susceptible.”

even cartilaginous;—that is to say, there is a double formation,—a double disease; and scirrhus is united with it. Now and then, bony particles are observed. Sometimes we see portions of it in a regular cyst. Instead of fine filaments, containing this brain-like matter, absolute cysts are seen; and sometimes portions resembling the white of boiled eggs,—coagulated albumen.

*Softening.*—This deposit, as it grows, softens down; and, like scirrhus and a scrofulous tubercle, it generally softens first in the centre. When it softens down, cavities are formed; or (perhaps we might say) cavities *become discernible*. These cavities chiefly contain blood; and, on washing this away, filaments or shreds floating in the cavity are distinguishable. If a portion of it be near the surface, the skin grows discoloured, the tumour adheres to the subjacent parts, and increases in size; or if the tumour be situated within, the serous membrane above it grows thin, till it gives way. The tumour, therefore, may ulcerate through the surface; or a serous membrane within may give way.

*Ulcerating Stage.*—When the tumour ulcerates, a fungus generally shoots forth, —but it is not firm,—like the fungus of scirrhus; but (on the contrary) is soft, easily torn, and bleeds very much. It is irregular, and of a dark red colour. When the fungus is very small, it exactly resembles the red soft polypi which grow from a mucous membrane; It grows very rapidly, and pours forth a fœtid sanious fluid; and people sometimes die, not from the irritation of the tumour, but from hæmorrhage. I had a patient who died from hæmorrhage, occasioned by one of these fungi in the bladder. There was, in the interior of the bladder, a fungus as large as a walnut, which never gave him any pain, or produced any irritation to the constitution; but which bled in spite of every thing which could be done. He discharged, not only bloody urine, but pure blood; and at last sunk under it. The hæmorrhage from a fungus of this description, is often very copious. Now and then portions will slough.

*Varieties.*—[Microscopical investigations have led to the establishment of the three following varieties, with respect to its intimate constitution:—

“Carcinoma medullare,” abounding in roundish formative globules, which make up the greater part of the medullary mass, though intersected by a delicate fibrous network. The specimens which Gluge examined, seem to have been of this kind. The globules differed in size;—the smallest being larger than pus-globules, and having a diameter of  $\frac{1}{125}$  of a millimetre.<sup>a</sup> They were irregular, though approaching the spherical form; their border was transparent; but dark points and round lines were distinguished on their uneven surface. He likewise observed crystals, of various kinds, in “fungus medullaris.” The author regards the formative globules of this variety of morbid structure, as very similar to those of common cancer, and to those which constitute the gray mass of “carcinoma reticulare:” a few points, or very minute granules, were often all that could be detected in their interior; but frequently, on making use of a high magnifying power, a nucleus may be seen;—just as in other forms of carcinoma. The size of these globules is about the same as in common cancer, though they are subject to great varieties in this respect.

2. “Carcinoma medullare,” with an exceedingly soft cerebriform base; composed of pale, elliptical bodies, without caudate appendages. The author<sup>b</sup> is acquainted with but one specimen, which he can refer to this class: it was a case of cerebriform fungus medullaris of the foot, and of the interior of the tarsal bones. With the exception of the vessels which were distributed to the diseased mass, its substance was almost entirely formed of uniform ellipsoidal corpuscles; which cohered but very slightly with each other. These corpuscles had a very pale hue, when looked at under the microscope; they were one-and-a-half or twice as large as the red particles of the blood, and equalled them in breadth. The author,<sup>b</sup> in no instance, observed a fibril proceeding from these bodies; nor did he ever see a single

<sup>a</sup> The millimetre is equal to thirty-nine hundredths of an inch, English measure.

<sup>b</sup> Müller.

nucleus, or a young cellule in their interior. A few very minute points were all that could be detected, by the highest magnifying powers.

3. "Carcinoma medullare," with caudate or spindle-shaped corpuscles. Sometimes, on tearing a piece of this kind of fungus medullaris, the torn surface will present a resemblance to a fibrous structure. This appearance is owing to several of the caudate corpuscles being arranged in one direction; as was observed in a case related by Valentin. The author<sup>a</sup> has seen a similar structure in several specimens of "fungus medullaris;"—sometimes interspersed in the midst of round, formative globules; at other times forming the greater part of the growth. According to the direction in which the caudate corpuscles are disposed, a radiated appearance is sometimes produced; at other times, the structure seems more tufted; while, in other instances, the direction of the corpuscles is so various, that the tumour does not display the slightest trace of fibrous texture. It is, indeed, not always easy (even when the caudate bodies are so disposed as to occasion a fibrous appearance) to tear the growth into tufts of fibres; although irregular portions of it may be broken off very readily. Frequently, however, the caudate corpuscles are arranged with great regularity. Their interior either contains a granular substance without any evident nucleus, or a nucleus with one or more nucleoli may be more or less distinctly seen. These corpuscles are prolonged at one or both sides, and in some rare instances at more than two sides, into fibrils of different length. They are cells, the development of which has been arrested, in the stage of transition from cells to fibres.<sup>b]</sup>

*Parts liable to be Affected.*—This is a disease which affects every part of the body. It will affect the testicle; and then it is called, by some, "soft cancer of the testicle;" or it may affect the breast, the eye, the uterus, ovaria, spleen, pancreas, liver, urinary bladder, brain, mesentery, and bones. It is very common in the eye of children. It is continually seen in the extremities; and the absorbent glands become contaminated, as they do in the case of common cancer. When the glands are affected, on being divided, they disclose nearly the same appearances as the original tumour; but there is this difference, it is said,—that they never send forth a fungus.

There are frequently in the neighbourhood smaller tubera,—circumscribed, but without a capsule; varying from the size of a pea to that of a walnut; of a pale grayish colour; and firmer than the original tumour; but they are the same disease.

*Secondary Encephaloid.*—This is a disease which commonly affects other organs secondarily; so that when persons have it in the breast, it is very common to find them gradually become the subjects of cough, and pulmonic disease; and, on opening them, we find similar tumours within. It is said that the organs which are affected secondarily, are never affected primarily. It is very common for many organs to become affected at once; and so great is the disposition to this disease, when there is any disposition at all, that Mr. Travers says he has never known a person survive four years, in whom he had operated for the extirpation of the disease.

*General Symptoms.*—The constitution becomes impaired. There is a cachectic look, even earlier than in scirrhus. Usually the person becomes emaciated, but now and then there is hardly any irritation at all; and sometimes a person may die of this disease in the stomach, without having suffered any pain at all; and frequently without any person having suspected the nature, or even the seat, of the disease. With respect to the case I mentioned<sup>c</sup> of the disease in the urinary bladder, the man, although he died from the hæmorrhage occasioned by it, never suffered the least pain. Even when the mass is very considerable, there is generally little or no pain; and sometimes there is little or no irritation of the constitution. The case differs very materially from scirrhus, therefore, in another respect. Scirrhus, I mentioned,<sup>d</sup> is almost always attended with violent deep lancinating pain; whereas,

<sup>a</sup> Müller.

<sup>c</sup> See Page 204.

<sup>b</sup> Müller on Cancer; Pages 63 to 65.

<sup>d</sup> See Page 201.

in encephaloid disease, there is very little pain, and sometimes there is very little irritation.

*Dubious Nature of the Tumour.*—A tumour of this description is exceedingly soft. Its external appearance is remarkably smooth and equal; and it gives the idea of fluctuation; so that I have known surgeons of great experience deceived in cases of this nature. They have imagined it was a collection of fluid, and plunged a lancet into it. I have seen this mistake occur over and over again;—from its extreme resemblance, with respect to the touch, to a tumour containing fluid. Frequently, for a length of time, the part will not be at all discoloured. It is soft and elastic; and it is these two circumstances that give the idea of fluctuation. The tumour, when taken out, is generally more or less round; and (as I stated before) it differs from scirrhus, in occurring at an early period of life. A kidney, taken from a child six years of age, has been seen, in which several portions of disease were of this nature. It seemed to be a mixture of various diseases;—some portions were scrofula; some were of scirrhus hardness; and in other parts there was certainly fungus hæmatodes.

*Causes.*—I do not know what gives the disposition to this disease. I am not aware of any external circumstances, which cause persons to be more liable to it; nor do I know whether it is hereditary. It is very probable that the disposition to it is hereditary,—exactly like the disposition to scirrhus; but it is carefully to be remembered, that this is not a painful disease, like scirrhus; and that it is a disease which affects the opposite period of life, to that in which scirrhus particularly prevails. Some consider it to be a mixture of scrofula and cancer.

### c. *Carcinoma Alveolare.*

[This form of carcinoma was described in Germany, by Otto, as a peculiar species of scirrhus of the stomach; and in France, by Laennec and Cruveilhier, under the names of “cancer gelatiniforme,” and “areolaire.”

The description which Otto has given, represents the main features of this degeneration (which always appears under one form) so exactly, that it may be detailed as affording a good illustration of the general anatomical characters of the disease.

*Anatomical Characters.*—The scirrhus occupied more than two-thirds of the whole stomach, and extended from the pylorus over a width of more than seven inches of its anterior and posterior wall. The walls of the stomach were so thickened, at the diseased parts, that they did not collapse. In several places, they were two inches and a half in thickness. The surface of the scirrhus part was uneven and tuberculated. Otto says that its substance differed so much from that of ordinary scirrhus, that, perhaps, it ought not to be referred at all to that class of diseases. The basis of its structure was composed of innumerable white fibres and laminæ, crossing each other in all directions, and having their interspaces occupied by cells, which varied in size from that of a grain of sand to that of a very large pea. Some of the cells were closed, but many of them communicated with each other: they all contained a very viscous, clear, perfectly transparent jelly. Externally, the diseased growth was covered by peritonæum, through which the half-projecting sacculi and cells were seen. The inner surface of the stomach was almost entirely deprived of its lining, wherever the disease extended; and most of the cells, both large and small, opened into the cavity of the stomach; into which, when firmly pressed, they poured their contents. The inner coats of the stomach were entirely destroyed by the disease. The muscular coat extended, for a short distance, into the morbid structure; but small cells, filled with jelly-like matter, were everywhere deposited between the muscular fibres.

The cases of “carcinoma alveolare” of the stomach which the author<sup>a</sup> has examined, correspond so exactly with this description, that he can but confirm it in

<sup>a</sup> Müller.

all points. At the commencement of the degeneration, the mucous and the muscular coats of the stomach swell; and sections of the latter present that striated appearance, observed in all forms of carcinoma of the stomach. The cellular structure containing the jelly-like matter, develops itself between the bundles of muscular fibre; but the like process takes place, at the same time, in the mucous membrane. In the early stages of the disease, the cells can be distinguished only by means of the microscope.

Occasionally, this cellular structure not only becomes developed in the stomach but also forms isolated nodules in different parts of the surface of the peritonæum. In M. Pockels's museum at Brunswick, the author<sup>a</sup> observed such masses of cells; which had formed on the abdominal peritonæum, in a case of "carcinoma alveolare" of the stomach. The smallest clusters of cells were scarcely larger than the head of a pin.<sup>b</sup>

*Symptoms.*—The symptoms of this form of cancer, which occurs most frequently in the stomach, are (according to Cruveilhier) more obscure than those of any other variety of carcinomatous disease. It is certainly less prone than other forms of cancer to give rise to symptoms of general reaction, and is more slow in producing the "cachexia cancerosa." Pockels observed neither pain nor vomiting; but the peculiar colour of the face which characterizes organic diseases of the stomach was not absent. Though most frequently met with in the stomach, "cancer alveolaris" is not by any means confined to this organ; for Cruveilhier has seen it in the small intestines, the rectum, the cæcum, the uterus, the ovary, and the bones; and the author<sup>a</sup> has also met with it in the intestines, in the female breast, in the great omentum, and especially in the peritonæum.

*Varieties.*—Cruveilhier distinguished between "cancer areolaire gelatiniforme," and "cancer areolaire pulsaté;" the cells of the former contain a transparent jelly, those of the latter a turbid pulsatous matter. He has observed the latter form in the uterus and in the bones.<sup>c</sup> The case which he relates of "cancer alveolaire pulsaté" of the skull, is very remarkable; and the representation he gives of it is very interesting.<sup>d</sup> The diseased bones were the frontal, the ethmoid, the inferior turbinated, and the vomer. The morbid growth extended both outwards and inwards; and had attacked the mucous membrane of the nose, and the dura mater. A somewhat similar structure was once observed by the author,<sup>a</sup> in a breast which M. Dieffenbach had removed. In this instance, the very firm puriform matter was contained within cells which had numerous communications with each other, and were lined by a membrane evidently vascular. Some lobules of this tumour were completely permeated by these cells; while other parts of the same growth presented no trace of this structure, but only the ordinary network of "carcinoma reticulare."

*Characters of the Jelly.*—The jelly-like matter contained in the cells, preserves its transparency even if kept in alcohol; and if expressed from the cells, and boiled, does not yield a trace of gelatine. After boiling, for eighteen hours, a portion of "cancer alveolaris" which had been macerated in alcohol, nothing was dissolved but a small portion of a substance somewhat allied to salivary matter, not precipitated by any re-agent,—not even by tannin; and of the existence of which evaporation afforded the only evidence.

In the remarkable case of "cancer pulsaté" of the skull, above-mentioned, M. Boutin Limousineau, assistant to M. Gay-Lussac, analyzed the yellow matter from the cells; and found that it contained caseine. The matter had, in this case, the colour of tallow.

<sup>a</sup> Müller.

<sup>b</sup> Engravings of "carcinoma alveolare" of the stomach may be found in Otto's "Seltene Beobachtungen zur Anatomie, Physiologie, und Pathologie;" Plate 1, Figure 4; Cruveilhier's "Anatomie Pathologique," Book 10, Plate 4; and Carswell's "Pathological Anatomy," Fasciculus 3, Plate 1, Figure 8.

<sup>c</sup> "Anatomie Pathologique;" Livre 24, Table 2, Figure 1; and Livre 27, Table 2.

<sup>d</sup> "Anatomie Pathologique;" Livre 21; Table 1.

*Microscopical Characters.*—From microscopic examination of “carcinoma alveolare” of the stomach, the author<sup>a</sup> obtained the following results. If the smaller cells are looked at under the microscope, they are found to contain (encased within them) many still smaller cellules; which, in their turn, include others of yet more diminutive size. In the smaller cells, the darkish yellow parietal nucleus is distinctly evident. Many cells, likewise, contain (free within their cavity) mere nuclei; as cytoblasts,<sup>b</sup> from which new cells are to be afterwards developed. The walls of the largest cells are distinctly fibrous, and their fibres run from one cell to another. Twice the author<sup>a</sup> observed rod-shaped crystals, in the jelly-like matter of preparations which had been kept in spirit; and on another occasion, he saw spindle-shaped corpuscles in the jelly from a “cancer alveolaris” of the breast.

*Mode of Development.*—The history of the development of “carcinoma alveolare,” corresponds exactly to that of the primitive formation of cartilage, and of the “chorda dorsalis,” as described by Schwann. The young cells are produced from cytoblasts, or nuclei developed in the interior of the parent cell; and, although the parent cell continues to increase in size, these young cellules (by degrees) fill up its cavity. At length, the walls of the young cells come in contact with each other, and they form, together with the parent cell (within which they are encased), one compound cell. Thus, the process of development goes on, till the larger cells on the internal wall of the stomach burst, and pour their jelly-like contents into its cavity. The fibres forming the walls of the largest cells constitute a nidus, within which younger generations of cells are developed. In order, however, to observe the manner in which the cells are encased one within the other, and the relation they bear to their nuclei, it is necessary to examine them in an earlier stage, and before their walls have begun to be split up into fibres.

The main point distinguishing “carcinoma alveolare” from “carcinoma reticulare” and “carcinoma simplex” seems to be, that, in the former, the cells continue to grow, and their walls become adherent to each other; while this progressive development, and mutual cohesion, do not take place in the delicate cellular globules of the two latter forms of cancer.<sup>c</sup>

*Summary.*—[The following proposition directly flows from numerous facts stated in the preceding pages:—A cancerous tumour, in all circumstances,—even should it remain single and stationary for years,—is but the local evidence of a general vitiation of the system. “But,” it may be inquired, “is not this a contradiction?—How is it possible that, if the organism at large be in a state of disease, a single spot shall alone manifest its presence?” We confess our inability to explain away this difficulty; but neither the fact of its existence, nor its inexplicability, shakes the solidity of the opinion advocated. All pathologists who have carefully investigated the history of the tuberculous affection, admit that local agencies, of whatever kind they may be, can never cause the production of a particle of tubercle,—that constitutional derangement must lead the way. Now here we have precisely the same difficulty to contend with;—a knot of tubercles may exist for years in the summit of a lung, and every other organ remain free to the last from the disease. Why this is so, we know not. These are the mysteries of pathology; and they are mysteries which, in the existing state of the science, it would be idle to attempt to penetrate.

From all that has been said, we may deduce the following definition of cancer. Cancer is a disease anatomically characterized by the presence of scirrhus, encephaloid, or colloid; originating in a general vitiation of the economy; and possessing the properties of assimilation, of reproduction, and of destroying life by a peculiar cachexia.<sup>d</sup>

[We shall conclude the consideration of carcinoma, with the following tabular view of the distinctive characters of the three species into which it is divisible;

<sup>a</sup> Müller.

<sup>b</sup> From *κύτος*, a cavity; and *βλαστός*, a germ.

<sup>c</sup> Müller on Cancer; Pages 50 to 54.

<sup>d</sup> “Cyclopædia of Practical Surgery,” Article “Cancer,” by Dr. Walshe; Volume I; Page 650.

taken from Dr. Walshe's article on "Cancer," to which frequent reference has been already made; and we may safely recommend an attentive perusal of that clear and comprehensive article, to the reader who seeks for a more extensive acquaintance with the subject than was consistent with the nature of the present work.]

## ENCEPHALOID

Resembles lobulated cerebral matter.

Is commonly opaque from its earliest formation.

Is of dead white colour.

Contains a multitude of minute vessels.

Is less hard and dense than scirrhus.

Is frequently found in the veins issuing from the diseased mass.

The predominant microscopical elements are globules, not always distinctly cellular, and caudate corpuscula.

Occasionally attains an enormous bulk.

Has been observed in almost every tissue of the body.

Very commonly co-exists in several parts or organs of the same subject.

Is remarkable for its occasional vast rapidity of growth.

Is frequently the seat of interstitial hæmorrhage, and deposition of black or bistre-coloured matter.

When softened into a pulp, appears as a dead white or pink opaque matter, of creamy consistence.

Subcutaneous tumours are slow to contract adhesions with the skin.

Ulcerated encephaloid is frequently the seat of hæmorrhage, followed by rapid fungous development.

The progress of the disease after ulceration is commonly very rapid.

Is the most common form under which secondary cancer exhibits itself.

Is the species of cancer most frequently observed in young subjects.

## SCIRRHUS

Resembles rinds of bacon, traversed by cellulo-fibrous septa.

Has a semi-transparent glossiness.

Has a clear whitish or bluish yellow tint.

Is comparatively ill supplied with vessels.

Is exceedingly firm and dense.

Has not been distinctly detected in that situation.

The main microscopical constituents, are juxtaposed nuclear cells; caudate corpuscula do not exist in it.

Rarely acquires larger dimensions than an orange.

Its seat, as ascertained by observation, is somewhat more limited.

Is not unusually solitary.

Ordinarily grows slowly.

Is comparatively rarely the seat of these changes.

Resembles, when softened, a yellowish brown semi-transparent gelatinous matter.

Scirrhus thus situated usually becomes adherent.

Scirrhus ulcers much less frequently give rise to hæmorrhage; and fungous growths (provided they retain the scirrhus character) are now more slowly and less abundantly developed.

There is not such a remarkable change in the rate of progress of the disease after ulceration has set in.

Is much less common before puberty.

## COLLOID

Has the appearance of particles of jelly, inlaid in a regular alveolar bed.

\*The contained matter is strikingly transparent.

Greenish yellow is its predominant hue.

(Its vessels have not, as yet, been sufficiently examined.)

The jellylike matter is exceedingly soft; a colloid mass is, however, firm and resisting.

The pultaceous variety has been detected in the veins.

Is composed of cells in a state of *emboîtement*.

Observes a mean in this respect.

Has so far only been seen in a limited number of parts.

Has rarely been met with in more than one organ.

Grows with a medium degree of rapidity.

Undergoes no visible change of the kind.

Has hitherto been observed in adults only.<sup>a</sup>

<sup>a</sup> "Cyclopædia of Practical Surgery," Volume 1; Page 647.

## SECTION III.—MELANOSIS.

*Nature of this Product.*—The next new formation of which I have to speak, is called “melanosis,” or “melanodes;” in which is deposited a mass of black substance; which, if cut, gives an unctuous smooth section; either uniformly dark coloured, or presenting certain shades; so as to be mixed up with patches, or streaks of paler coloured substance. Sometimes it is deposited in lobules, or a mass; and sometimes in plates. If a mass of this description be macerated, the black portion is separated; and this readily mixes with water, and stains the hand, linen, and paper;—just like Indian ink. It has neither taste nor smell. I never tasted it myself; but this is said to be the case; and it is worthy of notice, for considerations which I shall presently mention. It resembles in every respect the “pigmentum nigrum” of the eye, or the dye of the cuttle-fish; and the colouring matter of the hair, of the skin of negroes, of some parts of the brain, the bronchial glands (or ganglia of the lungs) of old people, and the placenta of some carnivora, may be similar. When it is washed out by water, the structure which is left after the separation of the black substance, is circumscribed, and more or less firm. When I say “*circumscribed*,” I am supposing that a piece of an organ is taken; that the part is healthy which is washed, and thus the black portion removed; after which there will remain a circumscribed substance, more or less firm, different from the rest of the organ in which the black matter lay. Although the character of this disease is blackness, we do not always have a decidedly black colour. There are shades of brown, and even of a yellow hue, as well as the black. The masses, or depositions, are not only of all sizes, but also of all shades.

*Analogous to Tubercle and Carcinoma.*—Sometimes a black mass of this description is thought to soften down; but that must be a rare occurrence. It has been seen that scirrhus softens down; and that tubercle softens down; but this mass very rarely, if ever, softens. It is, of course, a totally inorganic substance. It is like a tubercle in this respect,—that it never becomes organized; but it is unlike a tubercle in rarely, if ever, softening. A dark-coloured fungus will sometimes arise, from the part in which this black deposit has taken place; and so far it resembles “*fungus hæmatodes*.” The neighbouring glands will become affected;—I mean the glands which are connected with the absorbents of the part. Sometimes we have melanoid tubera, or tubercles (using the word “*tubercles*” in its common acceptation),—melanoid deposition in remote organs; so that the disease appears (like fungus hæmatodes or scirrhus) either in a primary or a secondary form;—beginning in one part, and being found afterwards (though not, of course, in so advanced a stage) in distant organs. There appears to be an analogy between this disease and “*fungus hæmatodes*,” as to the organs which are primarily and secondarily affected. There is the same order observed with regard to both circumstances. An absorbent gland, or a ganglion affected with this disease, might be sometimes taken for a mass of melanotic substance. The absorbent glands frequently have this substance deposited in them; and become blackened; and, of course, it is a gland blackened with a secretion of melanotic matter, and not a real mass of new matter, which is there. If we do not consider that the part which is examined is one in which an absorbent gland actually lies, it might sometimes be mistaken for a mass of this peculiar melanotic matter.

*Melanosis distinguished from Carcinoma.*—[Melanotic deposition not unfrequently occurs in carcinoma, more especially the encephaloid variety; and, on this account, Müller and other writers have considered it to be merely a variety of carcinoma. Dr. Walshe, in his Essay on Cancer,<sup>a</sup> has pointed out the following reasons for dissenting from this opinion:—1. Pure melanic pigment—no matter in what abundance accumulated—produces no other effects than those dependent on the mechanical obstruction caused by the mass it constitutes. 2. When melanotic

<sup>a</sup> “Cyclopædia of Practical Surgery,” Volume I; Page 614.

tumours produce the local and general symptoms of cancerous growths, they are found to be composed either of encephaloid or scirrhous (more especially the former), impregnated with black matter. 3. Neither the local nor general symptoms of carcinoma are modified in cases where melanic matter is found to pervade it. 4. Melanic matter is incapable of forming a tissue;—being an unorganized fluid, into which vessels have never been observed to penetrate.]

*Varieties of Melanosis.*—[Laennec, to whom we are indebted for the first description of this disease (the discovery of which is claimed by Dupuytren), described the four following forms of this affection:—1. Masses enclosed in cysts. 2. Masses without cysts. 3. Infiltration in the tissue of organs. 4. Deposition on the surface of organs. This classification, with some slight modification, was adopted by most writers; but the results of more recent researches on melanosis, and other morbid states and products which present the same distinctive physical characters as the former, suggest the propriety of a more comprehensive arrangement. The following tabular view, which Dr. Carswell has given, presents the leading features and varieties of this disease, in a very clear manner.]

### *Classification of Melanotic Formations.*

#### I. TRUE MELANOSIS.

Origin.	A modification of secretion.
Locality.	1. Tissues, systems, and organs. <i>a.</i> In the substance and on the surface of organs. <i>b.</i> In the cavities of hollow organs.
Form.	2. New formations. 1. Punctiform. 2. Tuberiform. 3. Stratiform. 4. Liquiform.
Seat.	1. Molecular structure of organs. 2. The blood.

#### II. SPURIOUS MELANOSIS.

Origin.	A. Introduction of carbonaceous matter. B. Action of chemical agents. C. Stagnation of the blood.
Locality.	Of first kind: the lungs. Of second kind: the digestive organs; the surface of serous and mucous membranes: the cavities of hollow organs; new formations.
Form.	Of third kind: the blood. Of first kind: uniform. Of second kind:—1. Punctiform. 2. Ramiform. 3. Stratiform. 4. Liquiform. Of third kind:—1. Punctiform. 2. Ramiform.
Seat.	1. The blood, contained in its proper vessels, or effused. 2. Pulmonary tissue; cellular and membranous. <sup>a</sup>

*Occurs in the Lower Animals.*—It has been seen, like the other deposits, in brutes; and particularly in the horse. Of all brutes, I understand, it is most frequently found in the horse; and it is said to occur most frequently in cream-coloured and spotted gray horses; and oftener in horses in the south of Europe than here. I do not speak from observation of my own; for I have not dissected

<sup>a</sup> Dr. Carswell, on "Melanosis," in the "Cyclopædia of Practical Medicine;" Volume 3; Page 86.

many brutes. So large are the masses which sometimes occur in horses, that they have occasionally been found, in the abdomen, to weigh thirty pounds. It is likewise seen in dogs, cats, rabbits, mice, and rats;—so curious have some people been, in the investigation of melanosis.

*Attacks all Parts of the Body.*—It not only attacks so many creatures, but it is said to attack all parts of the body;—chiefly, however, the lungs and the liver. Dr. Halliday mentions an instance of most intense melanosis in the human subject; where it existed, almost universally, in the subcutaneous and inter-muscular cellular membrane,—in the cellular membrane under the skin, and among the muscles; in the peritonæum, the pericardium, the pleura, the ovaria, the sternum, and the bones of the cranium;—so extensive sometimes is this deposition.

*Age at which it Occurs.*—This is a disease which does not occur early in life, like fungus hæmatodes; but rather resembles scirrhus in this respect;—seldom occurring till the individual has passed the middle age.

*Encysted or Diffused.*—Sometimes, though rarely, this substance (I do not use the word “matter;” because that conveys the idea of pus) is enclosed in a cyst. Most other deposits have a cyst; but it is only sometimes that this is found to be so enveloped. Occasionally, instead of being collected into a mass, it is completely diffused;—not merely in small scales and plates, but *generally* diffused along a membrane, mucous or serous; and when this is the case, it really is deposited, not upon the membrane itself, but rather in the cellular membrane immediately underneath it. I apprehend so because it is the cellular membrane that is liable to become cartilage and bone, and which is particularly liable to other diseases.

*On False Membranes.*—This disease, too, is not unfrequently seen in new membranes of the body; false membranes. When a serous membrane has been inflamed, or has had lymph deposited and afterwards organized, then the false membrane becomes cellular membrane, as mentioned before;<sup>a</sup> and these new false membranes are sometimes seen to contain a melanoid deposit.

*On Serous Surfaces.*—It is said, however, to be sometimes found on the surface of a serous membrane. It is right I should mention that I have not seen it; but it is said to have been found, not *underneath* the membrane, but lying on the surface. The parts around, probably, do not undergo any change except softening. Around this black deposit, the real natural parts of the body are found softened; but in general that is all, unless this disease coexists with another; and it is a very common thing for it to coexist with scirrhus, with “fungus hæmatodes,” and even with tubercles. Where, however, it exists alone,—where it is conjoined with no other disease, it seems to occasion nothing more than a mere softening of the surrounding parts.

*In a Fluid Form.*—Occasionally, this same substance would appear to exist in a fluid form. Occasionally we have a cyst filled with a liquid perfectly black; in which no difference has been observed from the mass I have now described, except that the one is liquid and the other solid. When this melanoid matter has been found in a fluid state, there is every reason to believe that it was formed originally fluid, and not softened down; because the usual course of the disease is for the mass to remain solid, however long it may last. When we see black fluid contained in a cyst, therefore, we must conclude (in general) that this substance had been originally formed with a disposition to remain fluid.

*Serous Membranes.*—We frequently see, upon a serous membrane, spots of melanosis; that is to say, perfectly black spots, which appear to be quite analogous to this affection. Indeed, one can hardly open many bodies, without seeing these spots upon certain serous membranes; particularly the peritonæum (towards the pelvis), the uterus, the bladder, and the rectum. These appear to do no harm,—they are perfectly innocent deposits; and sometimes we see very extensive deposits, superficially diffused; and in persons who are known not to have suffered at all from that circumstance.

<sup>a</sup> See Page 108.

*Mucous Membranes and Skin.*—It is frequently seen in mucous membranes, after they have been injured. After a mucous membrane has ulcerated, and has healed (which is very common in the intestines), the cicatrix is frequently blackened, more or less, with a deposit of this description. The deposition, as I mentioned before,\* is sometimes not exactly black, but merely grayish;—sometimes brownish, or even yellow; and this we see in the skin after an eruption, and after ulcerations of various kinds. After an eruption, the skin will sometimes remain black, but more frequently brownish; and, after an ulcer, it is very common for the legs to remain of a dark colour,—sometimes black, but more frequently of a brownish yellow. These, I presume, may be considered various shades of a similar deposit. The same is seen in the brain, after paralysis from effusion of blood into its substance. A deposition of this sort is sometimes seen in the mucous membrane of the intestines, after chronic diarrhœa. Occasionally, in the intestines, small points of black deposit are seen; as if a very fine powder had been sprinkled, in the finest possible way, upon the surface of the intestines. I do not know that it indicates any thing particular, but, every now and then, we see such points, extensively disseminated. When I first saw this, I imagined that it was some dirt or soot; but I found that it could not be washed off. It is not any thing exactly *upon* the surface; it is seen *through* the surface; but we cannot rub it off, unless we destroy the membrane itself. I have sometimes seen the middle of the tongue of a jet black, without any unhealthy state of the rest of the organ; and without sordes, or any dangerous symptom.

*Of the Entire Skin.*—I think there is a very curious circumstance analogous to this. I have never seen it; but there are, perhaps, nearly twenty cases on record within my reading (and beyond it there may be far more), of white persons who have become black. A change will now and then take place over the whole of the skin; so that a white person shall become entirely black. I have seen portions of the arm become black; but I have never seen an extensive change of that kind throughout the body. Others suppose (and I coincide with them) that this is a melanotic disease, on a very extended scale;—that melanoid substance is diffused solely upon the skin, and in the most extensive manner. When we consider, that if the disease be formed in a mass, it always bears a resemblance to the “*pigmentum nigrum*” of the eye, we must suppose that, when a white person is converted into a black, it is nearly the same affection.

*Black Alvine and other Excretions.*—Persons occasionally discharge from the stomach, or the intestines, a black liquid; and the discharge of this is called, in old authors, by the peculiar name “*melæna*,”—“the black disease.” This stuff, when perfectly black, has (I believe) no smell; at any rate, when it happens to be discharged pure, without fæces, it has no smell; and cases have been noticed, in which a large collection of precisely similar black liquid matter, has been found in the peritonæum. Some such cases are upon record. Dr. Prout has seen two or three instances (though I have not seen any myself) in which the urine was perfectly black;—not bloody, but black. The black secretion of the bronchia, in some people, is probably dependent on the same dye. When we come to consider yellow fever, we shall find that persons vomit stuff of a black colour, which is called “black vomit.” It is found to be tasteless; so that some have indulged themselves in drinking it. Others have put it into their eye, to see if it were acrid; and others have made an extract of it, and formed it into pills, and taken several in the course of a day; and they all concur in stating, that it is just like the melanotic matter of which I have just spoken, as deposited in solid masses;—tasteless, inodorous, and perfectly innocent when taken into the stomach.

*Nature of these Excretions.*—With respect to the discharge from the intestines, it may either be entirely black, or a little reddish,—so that we observe a slight hue of red in the black. Indeed, it may occur of various kinds, down to absolute

\* See Page 210.

blood. I think that these discharges which take place from the alimentary canal, are blood that has undergone a certain change.

*Discharge not Dangerous.*—Persons are exceedingly exhausted by this black discharge; but as it comes away through the intestines, it produces no pain, and (in general) no irritation;—nothing but exhaustion. It is admirably remedied by small and frequent doses of oil of turpentine;—just like hæmorrhage from the same parts. It appears to be (and I believe we must look upon black vomit as similar) an exceedingly mild substance;—as nearly like the blood as possible, except in colour.

*Pathology of Melanosis.*—What the change that has been undergone really is, I do not pretend to know, but the black urine, the black discharge from the intestines, the blackness of the skin, when a patient is converted (partially or generally) from white to black, the blackness of the peritonæum, of the mucous membranes, and of cicatrices in various parts of the body, and the black masses and substances in various organs,—all appear to be the same affection in different forms, and in different degrees; and it would appear to be merely blood which has undergone a very slight change. As taken from the horse, it is found (by analysis) to contain the elements of the blood,—fibrin, albumen, &c.; but nearly one-third is a highly carbonized substance,—probably altered cruor. Every other constituent is in far less proportion. In the cells of the ovaria, we often see a black substance,—frequently blood; and all shades may be traced between the two; so that blood here appears capable of being changed to this black substance.

*Prognosis.*—Melanosis appears to be perfectly harmless, except from the quantity of the substance which is formed. There may be an inconvenience arising from its bulk, its pressure, and its hardness; and of course when it is discharged, in a liquid form, there may be exhaustion from its quantity; but, independently of that, I believe that the disease is not one of any malignity. Still it is to be remembered, that it is very frequently united with malignant disease; for, in a mass of “*fungus hæmatodes*,” a black deposit often appears. This is not to be wondered at, when we consider that, in “*fungus hæmatodes*,” there is blood effused into the different cells. It is also seen in scirrhus, as well as encephaloid disease; and all these diseases are oftentimes observed to be mixed together in the same individual;—scirrhus, melanosis, and encephaloid disease, in one mass; but when confined to itself, I believe it is thought, by the greater number of persons, not to be a malignant disease.

#### SECTION IV.—KIRRHONOSIS.

*Definition.*—‘There is a disease, in which a substance of a yellow colour is deposited, in spots or patches, in the substance of the viscera, or upon the skin, or upon different membranes. A German author (Lobstein) says, that he has seen various parts of a membrane so coloured; and he calls this affection “*kirrhonosis*.”’<sup>a</sup> It seems particularly to affect the membranes of the head, chest, and abdomen; and when jaundice occurs in young children, Andral imagines that it is really this particular disease, and not true jaundice. I can give no opinion, from experience, respecting it. There is a species of jaundice which occurs in young children, and which is speedily removed by castor-oil; or which, even if no measures were adopted, would often cease spontaneously in a day or two; but besides that, there is sometimes jaundice, the disposition to which is congenital; for many families have died of it in succession. There are many children who are said to have jaundice; but which affection is supposed to be an instance of this yellow disease. Laennec calls it “*cirrhosis*,”<sup>b</sup> and says it is deposited in masses, or layers, or sometimes in a cyst,—such as we occasionally see in melanosis; and he conceives that a hard tuberculated liver, such as is seen in gin-drinkers, is an instance of this

<sup>a</sup> From *κίρρον*, yellow.

<sup>b</sup> A term under which it is treated and known by the majority of modern writers.

affection. I recollect having once seen, in the liver of a child who had scrofulous tubercles of the lungs, a cyst filled with this peculiar yellow matter. It is altogether a rare disease; unless the small brown tubercle of the liver be it. We are led to believe, from its general history, that it is an innocent affection;—that the deposit is as innocent as that of melanosis.

*Coexistence of many New Formations.*—When these new formations (tubercles, scirrhus, fungus hæmatodes, melanosis, and kirrhonosis) coexist in the body, it is nothing more than a fact analogous to the circumstances which I formerly stated, respecting *transformations*.<sup>a</sup> It was remarked, that the various transformations sometimes coexist in the same organ;—that cartilage may be found in one part of an organ, and bone in another. And so it is with respect to mere changes in size and consistence. We find them coexist in the same organ; so that one part of an organ will be indurated, and another softened;—one part hypertrophied, and another atrophied. Diseases of consistence, and of size, and those of transformation, sometimes blend together,—just like the diseases of new formations. And not only so; but new formations, and changes of consistence and of size,—all blended together in the same person,—are not unfrequently observed.

<sup>a</sup> See Pages 184 to 189.

## PART II.

## UNIVERSAL DISEASES.

THE diseases of which I have now spoken, are those which may affect almost any part of the body; namely, inflammation,<sup>a</sup> scrofula,<sup>b</sup> changes of consistence<sup>c</sup> and of size,<sup>d</sup> transformations,<sup>e</sup> and new formations.<sup>f</sup> I have spoken first of diseases which will affect any part. It is not meant that each of these diseases will affect any one part; but they may be situated either here or there. Besides these, however, there are other diseases which may be called “general,”—not from their being common to any part of the body; so that they may affect one person to-day in one part, and another in a different part to-morrow (as is the case with inflammation),—but because they are “general” in another sense;—they appear to affect the whole body together. Whether these general diseases have their origin in some one spot, I do not know; but, so far as I can observe, they exist (more or less) throughout the whole body. One of these is a disease called “anæmia” (*bloodlessness*);—a very curious disease; and there is another called “scurvy.” I do not know whether these diseases spring from the state of any one part of the body, more than of another; for we see a person bloodless throughout, without any local affection that can be discovered. They become pale,—blanched throughout, and excessively weak; and we cannot say that any one organ is labouring under disease, rather than another. So, in scurvy, the whole mass of blood, as well as of the solids, is affected;—so that these are general diseases in another sense; or, perhaps, we ought rather to say, they are *universal* diseases;—those being properly *general*, which are able to exist here or there. Those of which I shall next speak, therefore, are rather *universal* diseases; and perhaps the distinction I have drawn between *general* and *universal*, will be seen to be proper.

Again: there is another set of diseases which may themselves be local; but which produce effects so universal, that if they have really a local seat, it is at one spot in one patient, and at another spot in another patient. I refer to fevers; for there are various kinds of what is called “fever”—independently of eruptive diseases. Many persons speak of fever (whether intermittent, remittent, or continued) as having a particular locality; but I do not think they have proved the correctness of their assertions; and, according to our present state of knowledge,—though ready, of course, to change my course, when more knowledge is imparted to us,—I shall prefer considering these also as universal diseases.

Besides those general and these universal diseases, there are other affections, which consist of a mere affection of function; and in which, at least in many cases, there is no structural disease. It is possible that all diseases may be more or less structural; but I cannot help believing that some diseases are entirely *functional*. With respect to diabetes, for instance, I have frequently opened persons who have died of it; and if its pathology were estimated from an examination of the viscera, the disease would appear to be entirely functional. The labours of Bright and Prout have abundantly shown, that this affection (formerly thought to be only functional)

<sup>a</sup> See Page 71.<sup>b</sup> See Page 190.<sup>c</sup> See Pages 176 and 178.<sup>d</sup> See Pages 180 and 183.<sup>e</sup> See Page 184.<sup>f</sup> See Page 189.

depends upon a definite derangement in the processes of assimilation, and consequently in the circulating fluids. In cases of insanity, also, frequently no disease of the brain has been discovered. It appears to have been entirely functional. Of course the disease is *corporeal*; but “*corporeal*” is not “*structural*.” A disease may be *corporeal* and yet merely “*functional*,” for there may be no change of structure.

There are other diseases, entirely *mechanical*. Hernia is one of this class. Even fractures and luxations are classed, in systems of nosology, as diseases; but, at any rate, hernia is called a disease; and it is entirely mechanical.

There are other diseases which arise from another animal having taken up its abode with us. Such is the case with worms in the alimentary canal; and the existence of various insects upon the surface of the body.

Diseases, then, may be “*general*,”—attacking any one part; and there may be likewise “*universal*” diseases; which, according to our present state of knowledge, appear to be diffused throughout the whole body, without any particular locality. Again: it will be necessary to speak of diseases which are “*functional*”—affecting particular functions; not organic at all, but entirely functional; and affecting only special parts. Diabetes, for instance, as regards the kidney, and insanity as respects the brain, must be functional. Spasmodic asthma, also, is often a functional disease. Persons who have died of or with the disease have been opened, where no trace of disease could be found. “*Mechanical*” affections likewise, and the existence of parasitic animals,—“*parasitical*” diseases, are brought frequently under our notice.

But I shall content myself with the general account already given<sup>a</sup> of inflammation and “*structural*” diseases; and shall consider “*functional*,” “*mechanical*,” and “*parasitical*” diseases, not in general, but only in detail,—when speaking of the diseases of each part of the body. Previously to this, however, I must give an account of “*universal*” diseases.

---

## CHAPTER I.

### ANÆMIA.

*General Definition.*—The first of these universal diseases of which I shall speak, is called “*anæmia*,”—a word which explains itself;—“the want of blood.”<sup>b</sup> Blood is present; but there is a great deficiency of it. I have no doubt that the fault resides in some one particular part of the function of forming blood; but, in our present state of knowledge, we can only speak of it as a “*universal*” disease. When a person labours under this affection, we might state, *à priori*, what the symptoms must be. In the first place, there is great debility; in the next place, the skin is soft, and of a deadly pale wax-colour; in the next place, the white of the eye is bluish, the inner part of the mouth is colourless, the lips are exceedingly white, and even the tongue is pale. The pulse is, in general, about eighty; but exceedingly feeble, and very easily excited;—the least stimulus,—the least mental emotion, as well as corporeal movement, produces a great momentary acceleration. Respiration also is hurried on the least exertion. The appetite is bad; and it is said that there is constant thirst. There is œdema of the legs at last; and, finally, sweating;—sweating induced by the great debility. After death, the colour is much the same as it was during life;—the corpse is not paler than the living subject; for when his disease is intense, persons are really corpses in appearance.

<sup>a</sup> See Pages 71 to 216.

<sup>b</sup> From *an*, without; and *aima*, blood.

*Aggravated Species.*—So far, I think, one might beforehand portray the disease, merely upon reflection;—without ever having seen or read about it. But, in certain cases of this disease, the stools have been observed to be dark-coloured and fetid; the appetite to be bad; and almost every thing, at last, to be vomited. When persons have been opened, there has been found universal internal paleness, softness, and want of blood, and more or less excess of fluid in the serous membranes;—a fact corresponding with œdema of the legs, and with sweating in the last stages.

*Endemic Variety.*—This disease, in a peculiarly marked form, occurred formerly in France, to a great number of workmen in one particular gallery, at a coal-pit situated at Anzain, near Valenciennes. The disease was preceded by tormina, retching, green stools, thirst, and wasting, for ten or twelve days; and then the affection appeared, as I have now described it. It lasted for six, or even for twelve months; and then ended in death. At length, the proper treatment was discovered. A description of this endemic disease is given by Professor Halle. It might be called “endemic,” from having been confined to a particular mine, and even to a particular gallery in a mine;—as though it arose from some effluvia. Dr. Combe describes a similar case, in the first volume of the “Edinburgh Medico-Chirurgical Transactions.”<sup>a</sup> The patient was a corn-merchant’s son, in whom no evident cause for the disease could be discovered.

*Treatment.*—Mercury was given to the French patients, and did them a great deal of harm; for it is a state of the system in which mercury is very injurious. Opening one patient, and finding the internal vessels almost bloodless, they no longer gave mercury, but carbonate (or rather oxide) of iron in considerable quantity, with opiates, tonics, and good food; and the patients got well. They exhibited signs of improvement in the course of eight or ten days; and from that time the greater part, I believe, recovered. A similar occurrence took place at Dunkirk; and the treatment there was exactly the same (the exhibition of iron); and the patients recovered equally well. It was found, however, that relapse was very usual; and that the remedy had therefore to be continued for a considerable time. I believe the patients at Dunkirk, were persons who had been sent from the mines to which I before referred; but the same treatment was adopted, and was followed by the same success. In anæmia from loss of blood, as well as from *deficient formation* of it, iron is one of the best remedies. I must mention that Dr. Combe used both the sulphate and carbonate of iron; but he does not mention the doses, or the length of time they were given. Mercury, which appeared to be injurious in France, was also exhibited; as well as a number of other drugs;—so that the iron did not appear to have a fair chance.

---

## CHAPTER II.

### CHLOROSIS.

THERE is a disease common to young women, either about the time they ought to menstruate, or soon after they have begun to do so. It is called “chlorosis;”<sup>b</sup> and appears to be a state exceedingly similar to that of anæmia. It sometimes occurs to persons more advanced in life; and a similar affection also occurs to men. Strictly speaking, it is not chlorosis in *men*; because we say that one of the symptoms of chlorosis, is an absence of the menses;—the menses not appearing at the proper time of life, or retiring just after they have presented themselves. Of course, this is not a symptom of the disease in men; although, in them, when the actual

<sup>a</sup> Page 194.

<sup>b</sup> From *χλωρε*, green.

condition of the system is considered, it may be correctly termed "chlorosis." But let us consider *things*, rather than *words*. It is a fact, then, that men will sometimes fall into a state of anæmia and debility, very similar (in all appearance) to that state which in women is called "chlorosis."

These diseases, although they are not spoken of by authors as analogous affections, are all of the same family. There is a want of the production of blood; though wherein the defect consists, I do not know. In the cases which occurred in France, one would suppose that some deleterious substance affected the functions of the body. In chlorotic women, frequently, no cause can be discovered. In organic disease of the heart, patients will continually fall into a condition of the system, similar to that which we observe in chlorosis; but with palpitation ten times greater than ever occurs in that affection. In various visceral diseases, especially of the spleen and stomach, anæmia occurs.

[With reference to the question in dispute, as to whether the term "*chlorosis*" ought to be exclusively restricted to the anæmial state dependent upon disordered menstruation, the following practical observation on its varieties, by Dr. M. Hall, are important:—"Sometimes there is less pallor of the countenance and prolabia; but a ring of tumid darkness round the eye, and perhaps a tumid state of the upper lip. Sometimes the complexion is of a more yellow or *icterode* hue. Sometimes the complexion is of a peculiar *lead-colour*. There is sometimes a peculiar state of coldness, cold moisture, and lividity of the hands and fingers, and a lilac-hue of the nails; the tips of which often become white and opaque. The state of chlorosis consequent on hæmorrhage, also deserves to be distinctly noticed: there are paleness, and slight yellowness of the complexion, exanguious prolabia, a greater degree of loss of flesh, and great fluttering and nervousness. There are more chronic forms of this affection; in which there is a continued (though variable) state of sallowness, of yellowness (or *icterode* hue), of darkness, or of a wan, squalid, or sordid paleness of complexion; or a ring of darkness surrounding the eyes, and extending a little, perhaps, towards the temples and cheeks, and sometimes encircling the mouth;—without tumidity, paleness of the prolabia, and œdema.\*]

*Symptoms.*—When a woman becomes the subject of this disease (which is common), there is general paleness, with swelling of the face and ankles; weakness; a great sense of tension of the legs and feet; dyspnœa; palpitation; the pulse either quick or easily rendered so; and a deficiency of menstruation. These are the symptoms of chlorosis mentioned by authors; and they are, for the most part, exactly the symptoms that occur in the disease called "anæmia." I have no doubt the pathology, or proximate cause of these two diseases, is exceedingly similar. In women who have chlorosis, the alimentary canal is often very much disturbed; and that was the case with the Frenchmen whom I have mentioned.<sup>b</sup> There is sometimes a great derangement of the stomach; or, if the cause of hunger is cerebral, we must say "a derangement of mental feelings." Patients will long for all sorts of things; such as chalk, sealing-wax, or brown paper, with impunity. Such is the departure from the natural state of things. Very frequently, too, there is constipation. They will sometimes eat the most filthy things;—things that one would never think any human beings would touch, except cannibals. They will even take pleasure in offensive smells; and long to eat what they do eat in a privy. That, however, is an intense state of the affection.

*State of the Blood.*—[Among other changes which occur in the progress of chlorosis, there is none more constant than an impoverished condition of the blood; which is thin, light-coloured, and weakly coagulable;—being deficient in fibrin, and still more in the *proportion* of the red particles. To the latter cause is to be attributed the diminished temperature of the surface, and likewise the universal pallor and waxy state generally exhibited by the subjects of this disease. The deficiency of colour in the catamenia, and the pale stain which hæmorrhages from

\* "Principles of Medicine; by Marshall Hall, M. D." Page 205.

<sup>b</sup> At Page 218.

the nose leave on the linen, are also referable to the same cause. In aggravated cases, if blood be drawn from the arm, the crassamentum is observed to be of a pale rose-colour, and small in proportion to the serum. It is to be regretted that in this, as in most other cases of morbid blood, pathologists have contented themselves with a general observation of facts. The only analyses of chlorotic blood of which I<sup>a</sup> can find a record, are given by Mr. Jenkins, in two well marked cases of chlorosis; the one of a girl aged fifteen, the other of a young woman aged twenty-one. In these cases the blood contained 871 and 852 parts in a thousand (respectively) of water, instead of 780, which is the healthy standard; and the colouring matter amounted to 41.7 and 52 instead of 133. The albumen and salt were in the usual proportions.<sup>b</sup>

*Its Stages.*—[Chlorosis steals insidiously on the patient;—so insidiously, sometimes, that I<sup>c</sup> have known parents even to be unconscious of its existence, until it has been distinctly pointed out to them; although it may have attained its most marked form. It has three tolerably distinct stages;—the incipient, the confirmed, and the inveterate.

The incipient stage of this morbid affection is more particularly characterized by paleness of the complexion, an exanguious state of the lips, slight tumidity of the countenance, and puffiness of the eyelids,—especially the upper one. Along with this marked state of the countenance, there is sometimes a slight tinge of green, of yellow, or of slate-colour. In the confirmed stages of chlorosis, the state of pallor of the complexion is still more marked; and the tongue, as well as the lips, is exanguious;—perhaps with a slight lilac-hue in the upper lip. There is usually tumidity of the integuments in general, and of the eyelids in particular. In the inveterate or last stage, this state of the countenance is apt to be modified by a degree of loss of flesh on the one hand, and by increased œdema (perhaps partially disposed) on the other.

*State of the Tongue.*—In the first stage of this affection, the tongue is rather white and loaded; and somewhat swollen, and marked by pressure against the teeth. Its papillæ are enlarged; it is slightly formed into creases or folds; and its colour is rather pale. The gums and inside of the cheeks are, like the tongue, somewhat tumid; and the cheeks, like the tongue, are also impressed by the teeth. The mouth is generally clammy, and the breath tainted with a peculiar odour. In the confirmed stage of chlorosis, the tongue becomes clean, smooth, and exanguious; with a slight appearance as of transparency, and a slight lilac-hue. It is flat upon its surface, and still somewhat indented by pressure against the teeth. In the last stage, the tongue frequently becomes smoother still, and slightly shining; and I<sup>c</sup> have, in some cases, observed an odour of new milk in the breath of the patient.

*General Pallor of the Surface.*—In the beginning of this morbid affection, there is an increasing pallor of the general surface, hands, fingers, and nails; an opaque, white, and tumid state of the skin; a slight tendency to œdema of the calves of the legs, and ankles, and to loss of flesh. In the more confirmed stage, the skin is still smooth, but rather dry; and the integuments are exanguious, puffy, opaque, and perhaps yellowish, with the same or increased tendency to œdema. The nails are exanguious; and, in some instances, slightly split or exfoliated. In the confirmed stage, the appearances are the same, with the addition of some loss of flesh, and perhaps increased œdema. The nails are sometimes slightly split, and their tips opaque.

*Deficiency of Nervous Energy.*—The patient in chlorosis is languid, listless, sedentary, indisposed to exertion, easily overcome by exercise, nervous, low-spirited, and frequently a prey to singularities of temper. There is generally severe recurrent headache, or vertigo; sometimes heaviness for sleep; and sometimes an impaired state of the memory, and of the faculty of attention.

*Palpitation and Breathlessness.*—There is frequently palpitation, either recur-

<sup>a</sup> Dr. Babington.

<sup>b</sup> "Cyclopædia of Anatomy and Physiology," Volume 1; Page 423.

<sup>c</sup> Dr. Marshall Hall.

ring in attacks, or of a more permanent character: and, more frequently still, a sense of fluttering in the præcordia, with irregular action of the heart, or imperfect syncope. The pulse is sometimes rather frequent,—always easily accelerated. There is usually a degree of breathlessness experienced on any exertion; sometimes fits of dyspnœa, sometimes a sonorous cough.

*Pain of One or Both Sides.*—Frequently, also, there is a singular and peculiar pain of one or both sides, either together or alternately;—situate over the false ribs; and spreading a little upward, backward, or downward;—so as to occupy the space between the false ribs and the ilia. The recurrent nature, the particular situation, and the alternating character of this pain, are altogether peculiar and characteristic. The patient perhaps complains on pressure; but, on a careful examination, this pain will be found not to be aggravated by a deep inspiration. For this purpose the inspiration must be repeated; as it may appear, at first, to increase the pain; but afterwards it will be found not to do so.

*Appetite Impaired.*—The appetite is generally impaired, capricious, and even depraved;—inducing longings for some indigestible substances; such as acids or pickles, magnesia or chalk, tea-leaves, flour, grits, wheat, cinders, sand, &c. The patient likes to have some one of these substances in her mouth; but especially when affected by agitation or anxiety.

*State of the Bowels.*—The bowels, in the incipient stages, are always constipated. Afterwards this state alternates or leads to diarrhœa, and sometimes to hæmatemesis or melæna. The evacuations are usually scanty, dark-coloured and fœtid.

*State of the Menstrual Discharge.*—The flow and condition of the catamenia are, in general, very early affected in this disorder. They become irregular in their returns, inconstant or of short duration in their flow, defective in quantity, and pale in colour. Sometimes they are discoloured; sometimes they do not cease kindly, but are continued into a state of leucorrhœa; at other times, and especially in the latter stages of the disorder, there is amenorrhœa. In some instances, each return of the catamenia has been preceded and attended by much pain in the back, and in the region of the uterus.

*In the more Advanced Stage.*—In the inveterate stage of this disorder of the general health, the symptoms assume a modified but still more aggravated character. There is a very slow but progressive loss of flesh; the languor assumes the form of permanent debility; the œdema increases, and assumes the aggravated character of anasarca; the pulse becomes more constantly frequent; and there is altogether less of the character of functional derangement, and more of that of disease. The local complications become more permanent, or are renewed by the slightest causes; and, in some painful instances of this affection, the patient has been unable to bear the most ordinary occurrences of domestic life; and has, perhaps, been compelled to remain altogether in her room, or upon the sofa or bed. In this stage of the disorder, there is sometimes an almost permanent pain of the head, perhaps with intolerance of light or of noise; sometimes incessant pain of the chest, with tenderness, difficulty of breathing, and cough; and there are frequently pain and tenderness of the abdomen, with sickness, and constipation or diarrhœa. Various other symptoms prevail in different instances; such as locked-jaw, clenched hand, contracted foot, twisted limbs, palpitation or other forms of dyspnœa, fits of coughing, hiccup, retention of urine, &c.

*Pathology of Chlorosis.*—I<sup>a</sup> should despair of giving any thing accurate or specific, with regard to the pathology of this form of disorder of the general health. There appears to me<sup>a</sup> not to be a system, an organ, a texture, or even a fluid in the animal economy, which does not suffer in different instances of this multiform disorder. The complications of the more *acute* form of disorder of the general health, differ totally from those of the more *protracted*, both in their various seats, and in their nature;—the former affecting the more vital organs, the latter the

<sup>a</sup> Dr. Marshall Hall.

superficial textures. A similar remark equally applies to that form of disorder of the general health now under consideration.

There is in chlorosis a remarkable state of the capillary system of circulation, both of the vessels, and of the fluids. It is this which gives origin to the exanguinous appearance of the countenance, lips, tongue, gums, and general surface; to the tendency to œdema; and to different species of hæmorrhages, especially those of the mucous and cutaneous surfaces; such as epistaxis, melæna, hæmatemesis, and even purpura; and it is from this circumstance that the catamenia become almost colourless and aqueous. I<sup>a</sup> have observed the blood which has flowed from the nose scarcely to tinge the sheets; and that taken from the arm to resolve itself almost entirely into serum, with scarcely any crassamentum. This disorder affords, therefore, one of the most unequivocal examples of the humoral pathology.

*Causes.*—It would be difficult to trace the series of causes and effects in the pathology of this affection; but I<sup>a</sup> do think the *first* cause is in the state of the bowels; that a *concurrent* cause is the peculiarity of constitution just described; and that an *exciting* cause is the inactive and sedentary mode of life usually obtaining in female youth. The stomach suffers from its continuity with the intestines; the uterus possibly by contiguous, the head and heart by remote, sympathies. The pain of the side is peculiar, and too common to be a mere accidental complication, and it also, therefore, probably depends upon the state of the large intestines.

The state of the circulating fluids is probably deteriorated, from defective digestion and assimilation; and this deteriorated condition of the blood probably becomes a cause, in its turn, of impaired vital energy;—the heart and the brain being imperfectly stimulated. It is obvious, from these remarks, that blood-letting—so apt to be prescribed for painful affections of the head or side—should be employed with the utmost caution.

The state of disorder has sometimes been mistaken for organic disease; but its character is so distinct, that there does not appear to me<sup>a</sup> any danger of mistake with the careful observer. The state of the complexion, especially when it has assumed somewhat of the icterode hue,—has, indeed, frequently led to the suspicion of disease of the liver. The diagnosis is, however, readily established, on comparing the state of the lips, of the tunica conjunctiva, of the urine, and of the fæces; and by a careful examination of the region of the liver.

*Complications.*—The patient affected with chlorosis, is extremely subject to attacks of various local affections in a more continued form. It is, therefore, essential to distinguish the complications of this morbid affection from some sudden and some chronic diseases. The first case in which I<sup>a</sup> saw the necessity and the importance of these distinctions, had been successively treated as inflammation of the brain, and inflammation of the liver, by bleeding, blisters, and leeches, to an almost incredible extent;—the patient having been first subject to severe pain of the head, and afterwards to pain of the right side. The case was distinguished by the usual appearances and symptoms of disorder of the general health; and it was perfectly and even promptly removed by the appropriate remedies.

*Diagnosis.*—The diagnosis is founded upon the state of the countenance, of the tongue, of the general surface of the bowels, and of the catamenia; the multitude and variety of the other symptoms; the variable history of the case; perhaps, the suddenness and repetition of the attack; and the effects of remedies. The only difficulty is, when some topical inflammation comes on, in a patient previously affected with chlorosis. Even in this case the disease assumes a more settled and definite form, instead of the varying and complicated character of chlorosis; and may then be distinguished by a careful examination.

These observations strictly apply to the diagnosis of chlorosis with pain of the head, from inflammation of the brain or its membranes. In the latter disease, there are not the characteristic appearances and symptoms of chlorosis;—as observed in the countenance, tongue, general surface, and general symptoms; while there are,

<sup>a</sup> Dr. Marshall Hall.

on the contrary, the peculiar and definite symptoms of inflammation of the encephalon; which it would be out of place to mention here.

The cough and dyspnœa, the palpitation of the heart, the pain of the side, and the pain and tenderness of the abdomen, are to be distinguished from inflammation within the chest or abdomen, in the same manner, by comparing the general and local characteristics of chlorosis with those of each of these diseases; and by ascertaining the history, and observing the effects of remedies.

The pains of the side, or of the abdomen, so apt to occur as complications of chlorosis, are to be distinguished from pleurisy or peritonitis, by the same recurrence to the state of the complexion, tongue, and general surface, to the other symptoms, and by their own peculiar character. These pains, for instance, are less constant (both in situation and duration) than those of an inflammatory nature; and though sometimes aggravated by a deep inspiration, are not invariably so; especially on repeating the inspiration a third or fourth time. The accession of pain of the side, in chlorosis, is apt to be sudden; the side affected is sometimes changed; the degree of pain is sometimes extremely severe, at others less so; and there is more *expression* of pain than is permitted by the pain of *inflammation*; which represses the movements of respiration implied in the loud expression of pain.<sup>a</sup>]

*Treatment.*—I believe the best remedies for chlorosis, are the preparations of iron, which were found useful in France.<sup>b</sup> No medicine acts so beneficially as iron. I am not sure that the carbonate is better than any other preparation of that medicine; but with that I know practitioners will generally succeed. It is a disease not to be treated by bleeding, or profuse purging. The bowels are only to be maintained in a regular state. We must not allow a collection of trash to be formed in them; but, beyond that, purging does harm. All evacuants were found to do harm, in the cases of anæmia in France;<sup>b</sup> and I know from my own experience (which is necessarily very extensive, in so common an affection), that iron is by far the best remedy for chlorosis. Persons will lose their puffiness under it,—lose their difficulty of breathing; and will gain strength, and soon gain colour.

When I come to treat of diseases of the heart, an affection analogous to this will be met with. Persons will have violent palpitation, and become pale; and the state is not one indicating bleeding and purging; for in such a complaint as this, I know they will be made worse by those measures. But—very much to my surprise, when I first ventured on the practice, and frequently to the surprise of others—iron has remedied this morbid condition of the system, to a great extent. It will not cure organic disease; but when the heart, and body at large, have thus become almost bloodless, and extreme faintness has been induced by it,—so that a quick, irregular, and sharp pulse results,—the patient will experience the greatest relief from the exhibition of iron.

*Regulate the Diet.*—[With the view of filling the vessels with healthy blood, you should allow your patient a generous diet, apportioned to the powers of her digestive apparatus; and she may be supplied with all the food that she can take without producing symptoms of dyspeptic oppression, and offensive stools. Three meals, and perhaps four, she should take in the course of the day;—breakfast, an early dinner, tea, and a supper. In the way of peptic<sup>c</sup> preparative, you may recommend her, on rising in the morning, to take a tablespoonful of white mustard-seed, unbruised; and two or three pills, consisting of quinine, say one grain, and four grains of the best Cayenne-pepper (I<sup>d</sup> say “of the *best* pepper;” for some is little better than sawdust); and this pepper should be powdered thoroughly; and mixed up with a little mucilage, or any other combining substance which is likely to dissolve soon in the stomach. This peptic medicine may be taken four times a day; about half an hour before each of the four meals. The quantity of it ought

<sup>a</sup> Dr. Marshall Hall's “Commentaries on some of the Diseases of Women; Part I; Chapter 4; First Edition.

<sup>b</sup> See Page 218.

<sup>c</sup> Digestive; from *πεννω*, to ripen.

<sup>d</sup> Dr. James Blundell.

to be measured according to the effect produced;—warmth of the stomach, and a little gnawing pain there, being perhaps the best criteria that the medicine is in action. At breakfast she may use biscuits, or dry toast, or stale bread; with fresh butter, perhaps a new-laid egg, and one little cupful of hot black tea;—as hot as the mouth will bear it; in order that it may warm the stomach, and stimulate the inner membrane; for these hot drinks, though hurtful to the healthy, may be found very useful in a diseased stomach; and, much in the same manner as heated water is found to swell the hand immersed in it, and to excite the capillary circulation,—so as to produce reddening and perspiration,—the hot tea may be reasonably thought to produce its action on the capillaries of the stomach. The patient should be confined to one cupful of tea, that she may not deluge the stomach; for some women are very fond of taking tea in excess; and, in this way, they may overload the gastric cavity, and dilute the gastric juice, so as greatly to impair its digestive and solvent powers. At about one or two o'clock,—namely, five or six hours after breakfast,—another spoonful of the white mustard-seed and the peptic pill may be used;—being administered half an hour before the dinner. At this meal, be it observed, *boiled* meat is preferable to *roast* meat; *white* meat, to *red* meat; that which is *well*-done, to that which is *under*-done; the *inside*, to the *outside*; and potatoes, to every other vegetable. The food is to be thoroughly masticated, and eaten slowly. There should be no drink; or if there must be some, then take half-a-tumbler of very hot water; but, in general, the drink required ought to be taken two hours before dinner is begun. Toast-and-water, table-beer, or other aqueous fluids, are to be preferred. The pepper and the mustard-seed will supersede the alcoholic stimulus. Three or four hours after the dinner, the tea may be ordered;—not sooner, lest it should disturb the digestive powers. This meal is to be similar to the breakfast; and three or four hours after tea, the patient may sit down to supper, in the form of a very light dinner. With respect to the general beverage, my opinions are a little unsettled. To the alcoholic stimulus I<sup>a</sup> have an aversion, perhaps even a prejudice; and, certainly, if your patient under the use of this diet is acquiring strength, I<sup>a</sup> should not give much stimulant of this kind; but if not, then wine, or ale, or porter, or spirit, may be given; and of the four I<sup>a</sup> give a preference to spirit, in measured quantity, and diluted with four or five times its bulk of water. These fermented liquors, you may tell your patient, must never affect the head; and while she keeps clear of any unpleasant impression of this kind, she cannot be considered as indulging in marked excess. In general, in these cases, whatever beverage the patient uses, is better taken apart from the food;—say three hours afterwards; or, still better, two hours before. Both you and your patients may read Ludovico Cornaro on longevity, with great advantage.

*Change of Air and Bathing.*—Still more to invigorate the patient, if she is in the midst of a large town, you ought to send her to the sea-side, or into the country. Indeed, I<sup>a</sup> know of no means more efficacious for improving the digestive secretions, than change of air. I<sup>a</sup> do not here except mercury itself. You may sometimes have patients, for weeks together, in this large city,<sup>b</sup> with a metropolitan paleness of the cheek, and a commercial whiteness of the tongue; weak, sallow, emaciated;—rich and miserable;—in a word, labouring under gastric symptoms, too strong for your remedies; and yet these very patients, after having been eight or ten weeks, sometimes five or six only, in the country, acquire their full digestive powers, and become comparatively plump and fat. The cold shower-bath, where the patient is vigorous enough to react under it, may be used every day, or on alternate days. A dip in the ocean may be recommended, if the patient is at the sea-side; but it is better to defer the use of bathing, till the patient has a little recovered her strength. One of the best proofs of the salubrious action of the bath, is the production of a full glow; but if the body, after plunging, is pale-blue and chilly, or if local pains are felt, we must refrain. These different measures having

<sup>a</sup> Dr. James Blundell.

<sup>b</sup> London.

been carefully pursued, the chylopoietic<sup>a</sup> viscera having been strengthened and amended, the quantity of red blood having been increased, and the vigour of the system corroborated, should amenorrhœa<sup>b</sup> continue, you may have recourse to emmenagogue<sup>c</sup> remedies. Chlorosis is no medical objection to matrimony.<sup>d</sup>

## CHAPTER III.

### SCURVY.

*Definition.*—The word “scurvy” is said to be derived from some German words:—either from “*scharf-pocke*” (meaning “sharp” or “violent pock”) corrupted to “*scharbock*,” or from “*sharf-pocke*” (meaning “scab” or “scurf-pock”). However this may be, it is from the word “*scharbock*,” Latinized and corrupted, that “*scorbutus*” is derived; and a very barbarous word it is. From this we are said to have our English term “scurvy;” but I should rather think it came directly from the Danish word “*scurv*.” This name, “scurvy,” is used by the vulgar in a very indefinite sense;—being applied by them to any ill-looking chronic cutaneous disease; but in our profession it is restricted to a particular affection.

*Pathology of Scurvy.*—[It seems to be the universal opinion of those who have seen and written upon scurvy, that it owes its origin to a morbid change in the fluids, and especially in the blood. Notwithstanding this general belief, there has been no attempt (up to the present time) at any chemical examination of the properties of scorbutic blood; and we have only the general observation made by the surgeons of Lord Anson’s expedition (Messrs. Ettrick and Allan);—that in the beginning of the disease, it flows from the arm in different shades of light and dark streaks;—that as this advances, it runs thin and black, and after standing turns thick and of a dark muddy colour; the surface in many places being of a greenish hue, without any regular separation of its parts;—that in the third degree of the disease it is as black as ink; and though kept stirring in the vessels for many hours, its fibrous parts have only the appearance of wool or hair floating in a muddy substance;—and that, in dissected bodies, the blood in the veins is so fluid, that by cutting any considerable branch, the part to which it belongs may be emptied of its black and yellow liquor;—the extravasated blood being precisely of the same kind. The prevalence of scurvy, where there has been a long continued use of salted provisions, has given rise to the supposition that the salt itself actually finds its way into the circulation, and acts (as it is known to act on blood out of the body) by preventing its coagulation. This, however, is not correct; for the appearance of the blood, especially as the disease advances, is exactly the reverse of what it would be on the addition of salt; which—instead of making it black and causing it on standing to become thick, muddy, and of a greenish hue—would impart to it a fine scarlet tint, that would remain permanent until it began to putrefy.<sup>e</sup>]

<sup>e</sup> Article “Blood,” by Dr. Babington, in the “Cyclopædia of Anatomy and Physiology;” Volume I; Page 424.

*General Symptoms.*—This disease is characterized by a bloated surface; and by petechiæ, vibices, and ecchymoses. By "*petechiæ*," are meant minute dark red or livid points, little larger than the point of a pin; spots still larger than these are called "*vibices*;" and when instead of spots we have patches, the word "*ecchymosis*" is employed. They all relate to the same appearance, but denote a difference in extent. With respect to colour, these points, specks, or patches, are of a dark red or purple hue; but may contain all the shades which we see in bruises. In this disease, then, the surface is bloated; and upon it are seen points, specks, and patches, generally of a red or purple colour, but sometimes of all the shades which we see in common bruises. A very remarkable circumstance also attends the disease; and that is, the hardness of many parts, but particularly of the thighs. If the thigh of an individual labouring under scurvy (though only in a very slight degree) be examined, I believe it will be found generally hard, but more especially under the hams. In severe cases, I have seen it as hard as a board. I have not seen many cases of the disease; but in all of them I have noticed this circumstance. The gums are particularly affected. They are spongy, and bleed: and either they, or the breath, or both, send forth a very offensive odour. Such is the disease of the gums, that the teeth very frequently fall out; and, in addition to their being spongy and bleeding, they become enlarged and livid.

*General condition of the system in Scurvy.*—This is a disease of great debility; and the spirits are always very much depressed. So great is the weakness, that people very frequently faint from time to time; and the pulse is found to be feeble, and the surface of the body cold. Very often, ulcers form upon the surface, and discharge a thin and fetid bloody fluid; and, at last, a coagulum of blood is formed. The gums are in precisely the same predicament. The blood which is discharged and coagulates upon the ulcer, is with great difficulty separated from it; for it adheres to the ulcer and the flesh which is beneath; and, when this coagulum is removed, the flesh is found to be, like the gums, soft and spongy. If the clot be removed, it is instantly renewed. A fresh oozing of blood takes place; a second coagulum supplies the place of the first; and at length a fungus will sprout forth, —a soft, flaccid, dark looking fungus. It sprouts as fast as it is taken away; and is called, by sailors, "bullock's liver." It may attain an enormous size. If this fungus be repressed, a gangrenous tendency is frequently observed. The leg will swell, and become more spotted and painful. When a fungus sprouts forth from the "*dura mater*," after a fracture of the skull, it is known to be very dangerous to repress it. If the part be compressed, dangerous symptoms are very likely to ensue. In like manner, it is found injurious, in scurvy, to repress this "bullock's liver;" because the pressure induces a gangrenous tendency. The very slightest bruise, inflicted upon a patient labouring (to any considerable extent) under scurvy, will generally produce an ulcer of the description I have mentioned.

*Reappearance of Old Wounds.*—There are some other remarkable circumstances, respecting this disease. Old wounds, and even fractures, have a tendency to recur under it. Wherever an ulcer has existed,—wherever a solution of continuity in soft parts has taken place previously, although the parts may have been well cicatrized, yet under this disease the wound often opens again. Nor is this occurrence confined to soft parts; but even bones themselves (as just now stated) which were formerly fractured and repaired, become again disunited;—showing that the callus of bones is not so strong, as the original parts of the body; and that it suffers, when the rest of the bones do not. Another very singular circumstance connected with this disease, is the occurrence of hemeralopia,<sup>a</sup> (or, as some authors improperly say, nyctalopia<sup>b</sup>),—"night-blindness." Patients labouring under scurvy, frequently become blind, either altogether or in part, when night comes on.

*Causes.*—The great cause of this disease, appears to be the want of fresh ani-

<sup>a</sup> From *ἡμερα*, the day; and *ωφ*, an eye.

<sup>b</sup> From *νύξ*, νυκτος, the night; and *ωφ*, an eye.

mal and fresh vegetable food. It is on this account that the disease was formerly very common at sea; for, at one period, sailors were supplied with nothing but salt provision. So badly were ships formerly provided for, and so faulty was the general management, that in the year 1726, when Admiral Hosier sailed to the West Indies with seven ships, he buried his ship's company twice; and then died himself of a broken heart. Deaths to the amount of eight or ten a-day took place, formerly, in a moderate ship's company. The bodies, after being sewn up in hammocks, were washed about the deck, for want of sufficient strength, on the part of survivors, to throw them overboard. Lord Anson, in the year 1741, lost one half of his crew, by scurvy, in six months. Out of nine hundred and sixty-one men who sailed with him, only three hundred and thirty-five were alive at the end of the year; and, at the end of the second year, only seventy-one were fit for the least duty. Sir Gilbert Blane says, that the disease used to appear in about six or seven weeks from the beginning of sea-victualling.

*Historical Account of Scurvy.*—A better description of the dreadful mismanagement formerly prevalent, in regard to the navy, cannot be found than that in "Roderick Random." Smollett, both in that work and in his "History of England," gives an account of the armament which, about the same time that Lord Anson's expedition took place, was sent out against Carthage.<sup>a</sup> The description is from his own observation. He says<sup>b</sup> the provision consisted of putrid salt beef, salt pork, and musty bread. 'To the salt beef the sailors gave the name of "Irish horse;"—I suppose that it looked like horse-flesh, and that the contractors lived in Ireland. The salt pork came from New England; and was neither fish nor flesh, but savoured of both. The bread came from the same country; and the biscuit, like a piece of clock-work, moved by its own internal impulse;—owing to myriads of insects that dwelt within it. The butter was served out by the gill; and was exactly like train-oil thickened with salt; and though there was water enough to allow each man half-a-gallon daily, for six months, yet each had only a purser's quart a-day;<sup>c</sup> and this in the torrid zone, where a gallon would have been hardly

\* The expedition against Carthage, which took place in 1741, is described in "Roderick Random" (Volume 1, Chapter 31 to 34), and Smollett's "Continuation of the History of England" (Book 2, Chapter 7); as well as in a "Compendium of Voyages." The following particulars from "Roderick Random" (Volume 1, Chapters 25 and 33), as to the general management of the sick on board of ship, a hundred years ago, are valuable; from the author's opportunities of personal observation:—"At seven o'clock in the evening, Morgan visited the sick; and, having ordered what was proper for each, I assisted Thomson in making up his prescriptions; but when I followed him into the sick-berth (or hospital), and observed the situation of the patients, I was much less surprised that people should die on board, than that any sick person should recover. Here I saw about fifty miserable distempered wretches, suspended in rows, so huddled one upon another, that not more than fourteen inches space was allotted for each, with his bed and bedding; and deprived of the light of the day, as well as of fresh air,—breathing nothing but a noisome atmosphere of the morbid steams exhaling from their own excrements and diseased bodies; devoured with vermin hatched in the filth that surrounded them; and destitute of every convenience necessary for people in that helpless condition."

"The sick and wounded were squeezed into certain vessels, which thence obtained the name of 'hospital ships;' though (methinks) they scarce deserved such a creditable title;—seeing that few of them could boast of their surgeon, nurse, or cook; and the space between decks was so confined, that the miserable patients had not room to sit upright in their beds. Their wounds and stumps, being neglected, contracted filth and putrefaction; and millions of maggots were hatched amidst the corruption of their sores. This inhuman disregard was attributed to the scarcity of surgeons; though it is well known that every great ship in the fleet, could have spared one (at least) for this duty;—an expedient which would have been more than sufficient to remove this shocking inconvenience. But, perhaps, the general was too much of a gentleman to ask a favour of this kind from his fellow chief; who, on the other hand, would not derogate so much from his own dignity, as to offer such assistance unasked."

<sup>b</sup> "Roderick Random," Volume 1; Chapter 33.

<sup>c</sup> We loitered here [at the island of Vache] some days longer, taking in wood, and brackish water; in the use whereof, however, our admiral seemed to consult the health of the men, by restricting each to a quart a-day.—"Roderick Random," Volume 1; Chapter 31.

enough to repair the waste of perspiration.<sup>a</sup> It cannot be wondered, therefore, that scurvy formerly prevailed to the dreadful amount we have stated.

*Scurvy in London.*—The disease prevailed likewise on shore, however. Indeed scurvy, at one period, was one of the most fatal diseases in London; so that, even so late as the seventeenth century, there were from fifty to ninety deaths from it annually; and in the year of the plague,<sup>c</sup> there were not fewer than one hundred and five deaths. These frightful occurrences took place regularly; and not during a particular year. The same reason existed for the prevalence of scurvy in London, which produced it at sea; for the food of the Londoners was then salt beef and pork, with a little veal. The lower orders, in the time of Henry VIII, had very little else. The fact was, that only pasture land was then common; for very little was cultivated. Animals, therefore, could feed only during the summer and autumn. Hay being a later improvement, it was impossible to feed them longer than that period; and therefore, as the winter came on, they were killed and salted; and thus a store of provision was laid up until the next spring. Vegetables, too, were extremely scarce in those days: so that Catherine of Arragon, one of the numerous wives of Henry VIII, was actually obliged, in the beginning of the sixteenth century, to send to the Netherlands for a gardener to raise her a salad;—so ignorant were the gardeners of this country, of what is now considered within the reach of every body. Cabbages, and other vegetables, were not cultivated in England before the reign of Henry VIII. Government too, at that period, seemed to encourage the consumption of this meat; for the price of meat was fixed by law at one-twentieth of what it is now; whereas wheat was fixed at only one-tenth of its present price. Care was thus taken to have a good supply of *animal* food; but *vegetable* food was comparatively neglected. I may mention that, in 1700, a cabbage cost three pence; while, in 1760, it cost only one halfpenny. Such was the advance of art, and the increase of knowledge, that this great difference occurred in the price of a cabbage, at those two periods. Other greens too, at first, were proportionably dear; and vegetables were only used at that time on Sundays, and (as a great dainty) when people had company.

The use of salt or putrid meat, appeared to be the cause of scurvy. But it was not the salt; for salt, though taken in the greatest excess, will not occasion scurvy; and scurvy will take place where no salt is used. Nay, persons will have scurvy, who eat no meat at all; and therefore it is not this, but the want of other food,—the want of fresh animal and vegetable food,—that induces the disease. I have seen several,—not a large number,—but several cases of scurvy, in individuals who had eaten no meat at all. They had been deprived of meat of every description; and it arose in them from the want of food. In the “Transactions of the College of Physicians,”<sup>d</sup> two cases are mentioned by Dr. Francis Milman, of women that had the scurvy in the country. They had eaten no meat whatever; but had lived on tea and bread, after having been accustomed to better food. Sea and land-scurvy, I believe, are exactly the same; and Dr. Musgrave (who published a work on the

<sup>a</sup> Instead of small beer, each man was allowed three half quarters of brandy or rum; which were distributed every morning, diluted with a certain quantity of water, without either sugar or fruit to render it palatable; for which reason this composition was not unaptly styled “*necessity*.” This fast must, I suppose, have been enjoined by way of penance on the ship’s company for their sins; or rather with a view to mortify them into a contempt of life;—that they might thereby become more resolute and regardless of danger. How simply, then, do those people argue, who ascribe the great mortality among us to our bad provision and want of water; and affirm that a great many valuable lives might have been saved, if the useless transports had been employed in fetching fresh stock, turtle, fruit, and other refreshments, from Jamaica and other adjacent islands, for the use of the army and fleet;—seeing, it is to be hoped, that those who died went to a better place, and those who survived were the more easily maintained. After all, a sufficient number remained to fall before the walls of St. Lazar; where they behaved like their own country mastiffs; which shut their eyes, run into the jaws of a bear, and have their heads crushed for their valour.—“*Roderick Random*,” Volume 1; Chapter 33.

<sup>d</sup> Volume 2; Page 471.

gout, in 1703) mentions, that this disease was common in Somersetshire;—so that it prevailed at sea, in large towns, and in the country.

There can be no doubt that many circumstances conspire to the production of this disease. Cold and the want of exercise unquestionably encourage it; for sailors are observed to suffer in cold latitudes, when they are placed under precisely the same circumstances, with the exception of latitude, in which they escape it in warm climates. This fact strikingly illustrates the effect of cold. As to the want of exercise, Captain Cook says that the people of Kamschatska, who are habituated to hard labour, never have the scurvy; while the Russians and Cossacks in garrison, who live in the greatest indolence, are subject to it. Sir Gilbert Blane says, that only the prime seamen, who were exempted from pumping, were attacked with scurvy. He instances the case of a particular ship's crew; and says, that the prime seamen suffered from the disease; whereas those who were obliged to work hard at the pump, from time to time,—the ship having proved leaky,—escaped. Moisture is also said to have a considerable effect; especially, I presume, when united with cold. La Perouse attributes the prevention of scurvy, in his crew, very much to the vessel being kept dry by fumigation, and by braziers of hot coals. Captain Parry ascribes the first case of scurvy, in one of his expeditions, to moisture. When scurvy prevailed at the Penitentiary at Millbank, a few years ago, it was observed, that the persons employed in the kitchen always escaped; perhaps, however, they got better food than the rest, or more of it; but, at any rate, they had a warmer place. Captain King told Dr. Macmichael, (as he stated in a paper<sup>a</sup> read at the College of Physicians,) that, in a voyage round the south coast of America, no cause of scurvy was apparent,—the crew having had plenty of lemon-juice,—except that there was a remarkably cold and moist state of the atmosphere. I do not believe that moisture alone will occasion it; but moisture certainly aggravates the effects of cold in this disease; as it does in all others.

*Mode of Prevention.*—The difference between ships' crews now and formerly, is very striking. While the crew of Lord Anson suffered so much in a voyage round the world, that of Captain Cook, in a voyage subsequently performed, suffered nothing. The difference arose from this circumstance:—Captain Cook had a good supply of portable soup, sour crout, and fresh meat; and he kept his men in regular exercise; and took care, at the same time, that extreme cleanliness and ventilation should be observed. In addition to this, they were away from land only about three weeks, on their longest cruise; although absent from home so long. Such measures as he adopted will generally prevent scurvy, even if there be no fresh provision on board, provided there is a supply of lemon-juice; and sometimes, in spite of the neglect of all these particulars, lemon-juice alone will prevent it.

*Remedies for Scurvy.*—The great remedy for scurvy, is fresh food,—animal and vegetable. Farinaceous vegetable substances alone are insufficient; but when fresh meat cannot be procured, I believe lemon-juice will be found the most efficacious medicine. The effects of lemon-juice on the disease are speedy and wonderful;—so wonderful, that the compiler of “Lord Anson's Voyage,” after describing the disease, and the horrors which took place from its ravages, says that the cure of such a complaint seems impossible, by any remedy or any management that can be employed.<sup>b</sup> Scurvy was formerly set down, without hesitation, as an incurable

<sup>a</sup> Published in the “London Medical Gazette;” Volume 8; Page 184. (No. 179; May 7, 1831.)

<sup>b</sup> In Anson's report of March 31 [1741], he makes the first mention of the scurvy, as follows:—“Men falling down every day with scorbutic complaints.”

Soon after our passing Straits Le Maire, the scurvy began to make its appearance among us; and our long continuance at sea, the fatigue we underwent, and the various disappointments we met with, had occasioned its spreading to such a degree, that at the latter end of April, there was but few on board, who were not, in some degree, afflicted with it; and, in that month, no less than forty-three died of it on board the Centurion. But though we thought that the distemper had then risen to an extraordinary height, and were willing to hope, that as we advanced to the northward its malignity would abate; yet we found, on the contrary, that in the month of May we lost nearly double that number; and as we did not get to land till the middle of June, the mortality went on increasing; and the disease ex-

disease;—not only as a disease incurable *then*, but as being so formidable in its nature, that it *never* could be cured; and yet, in almost every case, we can now cure it with the utmost facility. It is not only lemon-juice that will cure it, but all the hesperideæ; such as the lime, and Seville and unripe China oranges. Malt and sour crout are thought to have a similar property. Lemon-juice is preserved by mixing one-tenth of spirit with it. The custom, I believe, is to give three table-spoonfuls every morning to each man, for the purpose of keeping the disease away. One ounce of lemon-juice, with one ounce and a half of sugar, is the present navy-allowance; and it is said that scurvy rarely occurs now in the longest voyage. Citric acid is thought to be inferior to lemon-juice. During the nine years previous to this supply, the average number of sick sent to the hospitals, was one man in three and nine-tenths of the whole navy; while, in the succeeding nine years, it

tended itself so prodigiously, that after the loss of about two hundred men, we could not at last muster more than six fore-mast men in a watch capable of duty.

This disease, so frequently attending all long voyages, and so particularly destructive to us, is surely the most singular and unaccountable of any that affects the human body. For its symptoms are inconstant and innumerable, and its progress and effects extremely irregular; for scarcely any two persons have the same complaints, and where there hath been found some conformity in the symptoms, the order of their appearance has been totally different. However, though it frequently puts on the form of many other diseases, and is therefore not to be described by any exclusive and infallible criterions; yet there are some symptoms which are more general than the rest; and therefore, occurring the oftenest, deserve a more particular enumeration.

These common appearances are large discoloured spots dispersed over the whole surface of the body, swelled legs, putrid gums, and (above all) an extraordinary lassitude of the whole body, especially after any exercise, however, inconsiderable; and this lassitude at last degenerates into a proneness to swoon on the least exertion of strength, or even on the least motion. This disease is likewise usually attended with a strange dejection of the spirits, and with shiverings, tremblings, and a disposition to be seized with the most dreadful terrors on the slightest accident. Indeed, it was most remarkable, in all our reiterated experience of this malady, that whatever discouraged our people, or at any time damped their hopes, never failed to add new vigour to the distemper; for it usually killed those who were in the last stages of it, and confined those to their hammocks who were before capable of some kind of duty; so that it seemed as if alacrity of mind, and sanguine thoughts, were no contemptible preservatives from its fatal malignity.

But it is not easy to complete the long roll of the various concomitants of this disease; for it often produced putrid fevers, pleurisies, the jaundice, and violent rheumatic pains; and sometimes it occasioned an obstinate costiveness, which was generally attended with a difficulty of breathing; and this was esteemed the most deadly of all the scorbutic symptoms. At other times, the whole body, and especially the legs, were subject to ulcers of the worst kind; attended with rotten bones, and such a luxuriance of fungous flesh, as yielded to no remedy. But a most extraordinary circumstance, and one that would be scarcely credible upon any single evidence, is, that the scars of wounds which have been for many years healed, were forced open again by this virulent distemper. Of this, there was a remarkable instance in one of the invalids on board the *Centurion*, who had been wounded above fifty years before, at the battle of the Boyne; for though he was cured soon after, and had continued well for a great number of years past, yet, on his being attacked by the scurvy, his wounds, in the progress of his disease, broke out afresh, and appeared as if they had never been healed; nay, (what is still more astonishing,) the callus of a broken bone, which had been completely formed for a long time, was found to be hereby dissolved, and the fracture seemed as if it had never been consolidated. Indeed, the effects of this disease were, in almost every instance wonderful; for many of our people, though confined to their hammocks, appeared to have no inconsiderable share of health; for they ate and drank heartily, were cheerful, and talked with much seeming vigour, and with a loud strong tone of voice; and yet, on their being the least moved,—though it was only from one part of the ship to the other, and that in their hammocks,—they have immediately expired; and others, who have confided in their seeming strength, and have resolved to get out of their hammocks, have died before they could reach the decks, and it was no uncommon thing for those who were able to walk the deck, and to do some kind of duty, to drop down dead in an instant, on any endeavours to act with their utmost vigour;—many of our people have perished in this manner, during the course of this voyage.—“*A Voyage round the World, in the years 1740, 41, 42, 43, and 44. By George Anson, Esq., Commander in Chief of a Squadron of His Majesty's Ships, sent upon an Expedition to the South Seas. Compiled from papers and other materials of the Right Honourable George, Lord Anson; and published under his direction. By Richard Walter, M. A.; Chaplain of his Majesty's Ship the Centurion, in that Expedition.*” Book 1; Chapters 8 and 10. (Smith's “*Standard Library*” Edition; Pages 25, 31, and 32.)

was only one in eight and four-tenths. The juice is also said to improve the general health. I may mention, as a good illustration of the power of lemon-juice, that the ship "Suffolk" left England in April 1794, and had no communication with land for twenty weeks and a day; and yet, during all that time, she had only fifteen sick, and those slightly. They were soon cured by an augmentation of the first allowance of two-thirds of an ounce; and, at her arrival, not one had the scurvy. In 1800, the channel-fleet—consisting of twenty-four ships of the line, besides smaller vessels—had no fresh provisions for sixteen weeks; but they had plenty of lemon-juice, and not a single instance of scurvy occurred; whereas, in 1780, the channel-fleet could not keep at sea beyond ten weeks, and was worn out with scurvy and fever. Two thousand five hundred men were sent into port with the scurvy. We read in Purchas's "Pilgrim,"<sup>a</sup> that Commodore Lancashire sailed from England, with four ships, for the Cape of Good Hope, on the second of April; and arrived at Saldanha Bay on the first of August. The Commodore's own ship was in perfect health;—owing to the administration of three tablespoonfuls of lemon-juice, every morning, to each of his men; whereas the other ships were so sickly, as to be unmanageable for want of hands; and the Commodore was obliged to send men on board, to take in their sails, and hoist out their boats.

*Antiquity of Lemon-Juice as a Remedy.*—This disease, of course, occurred in ancient times. It was known in the Roman army in Germany, and also in the "Holy Wars" (as they were impiously denominated); but it was first particularly noticed in the crew of Vasco di Gama, in 1497. We find it mentioned by Pliny, as occurring in the Roman army, under the command of Germanicus. But with respect to the remedy, its discovery appears to have been left for modern times; but still not for *recent* times; for we find it mentioned as far back as 200 years ago. There is a curious fact connected with it, and one which is very instructive;—as teaching us not to despise any thing without good reason. It is said that when the London College of Physicians was applied to by Government, for a cure for scurvy, they advised vinegar, which has very little power in the affection; and that a fellow of the College, who wrote on the disease in 1753, never adverts to lemon-juice at all in his treatise; and yet that, two hundred years ago, it was mentioned in the "Surgeon's Mate, or Military and Domestic Medicine;"—a work published in 1636, by "John Woodall, Master in Surgery." He ends his praise of it by saying, that he dare not write how good a sauce it was, with meat; lest the chief in the cabin should waste it, to save vinegar. It is said to have been mentioned even still earlier,—in Purchas's "Pilgrim," published in 1600. Dr. Lind, of Haslar Hospital, revived the knowledge of it, more than one hundred years afterwards. He stated its peculiar powers, in the third edition of his work on the "Diseases of Seamen," in 1772; but even then it was not brought generally into use; and the navy actually suffered most frightfully from scurvy till 1795. Although the remedy was mentioned two hundred years ago, and again in a well known surgical work in 1636, yet the navy suffered from the want of it till 1795. Earl Spencer, the father of the present Earl,<sup>b</sup> was then at the head of the Admiralty; and, on the representations of Dr. Blair and Sir Gilbert Blane (who were commissioners of the board of sick and wounded seamen), a good supply of it was ordered by Government. In less than eighteen months afterwards, there was not a case of scurvy in Haslar Hospital. In 1780, there had not been fewer than 1457; in 1806, and in 1807, there was but one.

So great is the effect of this remedy, that we find the following passage in Sir William Herschel's work, published in Dr. Lardner's "Cyclopædia," on the cultivation of the physical sciences:—"At present, the scurvy is almost completely eradicated in the navy;—partly, no doubt, from an increased and increasing attention to general cleanliness, comfort, and diet; but mainly from the constant use of a

<sup>a</sup> Volume 1; Page 149.

<sup>c</sup> "Preliminary Discourse on the study of Natural Philosophy;" Chapter 3; Paragraph 41. ("New Edition;" Pages 52 to 54.)

simple and palatable beverage.—the acid of lemon, served out in daily rations. If the gratitude of mankind be allowed on all hands, to be the just meed of the philosophic physician, to whose discernment in seizing, and perseverance in forcing it on public notice, we owe the great safeguard of infantile life;<sup>a</sup> it ought not to be denied to those, whose skill and discrimination have thus strengthened the sinews of our most powerful arm; and obliterated one of the darkest features, in one of the most glorious of all professions.

*Prevention of Scurvy.*—The scurvy is now prevented, by great attention to cleanliness; by giving sailors food as wholesome as possible; by attention to exercise and cheerfulness; and by a regular supply of lemon-juice. In spite of all this, however, sporadic cases still occur; but, in general, that is all. I have myself had several cases of this disease in London; and some of them were in persons who had never been at sea, and who had eaten no salt meat; but who had been deprived of food nearly altogether. Others were sailors, who came on shore labouring under the disease; for, in merchant-ships, there is frequently the greatest neglect. I had one patient, a few months ago, who had been sixteen weeks at sea; and had nothing but biscuit and the hardest salt beef, during the whole voyage. There was no medical man on board; but that, I suppose, is unavoidable in small ships. He was, as might be expected, labouring under scurvy to a great extent; and he said that several of the crew had died. I am not sure that the lemon-juice, which I gave these patients as a matter of course, did them any good; for they were allowed fresh meat and greens every day, with porter, and other articles of good diet; and this was quite sufficient, I am sure, to cure the disease.<sup>b</sup> I gave them lemon-juice in addition; because we have such great authority for its employment. However,

<sup>a</sup> Alluding to Dr. Jenner, and the Cow-Pock.

<sup>b</sup> All the hands we could muster, capable of standing at a gun, amounted to no more than seventy-one; most of which number, too, were incapable of duty; but, on the greatest emergencies, this was all the force we could collect, in our present enfeebled condition, from the united crews of the *Centurion*, the *Gloucester*, and the *Tryal*; which, when we departed from England, consisted altogether of nearly a thousand hands.

When we had furled our sails, the remaining part of the night was allowed to our people for their repose,—to recover them from the fatigue they had undergone; and in the morning a party, of which myself was one, was sent on shore [at Tinian] well armed, to make ourselves masters of the landing-place;—as we were not certain what opposition might be made by the Indians on the island. We landed without difficulty; for the Indians had fled into the woody parts of the island. We found on shore many huts which they had inhabited; and which saved us both the time and trouble of making tents. One of these huts, which the Indians made use of for a store-house, was very large; being twenty yards long, and fifteen broad. This we immediately cleared of some bales of jerked beef (which we found in it), and converted it into a hospital for our sick; who, as soon as the place was ready to receive them, were brought on shore;—being, in all, a hundred and twenty-eight. Numbers of these were so very helpless, that we were obliged to carry them from the boats to the hospital upon our shoulders. Notwithstanding the great debility and the dying aspects of the greatest part of our sick, it is almost incredible how soon they began to feel the salutary influence of the land; for, though we buried twenty-one men on this and the preceding day, yet we did not lose above ten more during our whole two months' stay here; and, in general, our diseased received so much benefit from the fruits of the island, particularly the fruits of the acid kind, that, in a week's time, there were but few who were not so far recovered, as to be able to move without any help.

This place was not only extremely grateful to us, from the plenty and excellence of its fresh provisions, but was as much perhaps to be admired for its fruits and vegetable productions; which were most fortunately adapted to the cure of the sea-scurvy, which had so terribly reduced us. For in the woods there were inconceivable quantities of cocoa-nuts, with the cabbages growing on the same tree; there were besides, guavas, limes, sweet and sour oranges, and a kind of fruit peculiar to these islands, called by the Indians "rima," but by us "the bread fruit;"—for it was constantly eaten by us during our stay upon the island, instead of bread; and so universally preferred to it, that no ship's bread was expended during that whole interval.—Besides the fruits already enumerated, there were many other vegetables extremely conducive to the cure of the malady we had long laboured under;—such as water-melons, dandelion, creeping purslain, mint, scurvy-grass, and sorrel; all which, together with the fresh meats of the place, we devoured with great eagerness; prompted thereto by the strong inclination which nature never fails of exciting, in scorbutic disorders, for these powerful specifics.—"*A Voyage round the World*," by George Anson, Esq. Compiled by Richard Walter, M. A. Book 3; Chapter 2. (Smith's "Standard Library" Edition; Pages 94 to 96.)

some persons now begin to say that the lemon-juice does no good;—that the benefit entirely arises from the other means that are employed; and that the neutral salts, particularly nitre, answers a better purpose. I dare not say, however, that authority respecting the powers of lemon-juice, so accumulated and so immense as it is, is at all to be disputed. I certainly cannot but think that, till we have further facts, it is our duty in every case to supply lemon-juice, or similar things (if that cannot be obtained);—in the hope of doing away with the ill effects, which a want of fresh food occasions. I may also mention that, with regard to local applications, lemon-juice is found to be one of the best. When there is a scorbutic ulcer, I believe a slice of lemon laid upon it is one of the best applications that can be employed. Père Lebat is said to have mentioned this in his “Voyage to the Antilles.”

*Nature of Scurvy.*—This disease, I should say, is of a chemical nature,—if any one be so. In one sense, the constitution is not at all in fault. All the fluids and all the solids appear to be changed; but we have only to give a different chemical state to the body, and the disease is cured. We need give nothing which acts by a specific operation;—no drug, I mean, which acts as a medicine; but we employ fresh articles of diet, and thus remedy the depraved constitution of the whole mass of solids and fluids.<sup>a</sup> I have, therefore, mentioned this disease, before I came to any of those which are clearly seated in particular parts. I am not aware that it attacks any one part in particular. It seems to be a cachectic state of the whole frame; and if any affection be an instance of “universal disease, I should certainly say that it was scurvy.

There is an affection very similar to the scurvy in some respects, which has been arranged and described, by Willan, among cutaneous diseases; and which is called “purpura.” Some are of opinion that this is the same as scurvy; but I cannot think so;—for reasons which I will state when speaking of diseases of the skin.

## CHAPTER IV.

### INTERMITTENT FEVER.

FEVERS are divided, generally, into three kinds;—intermittent, remittent, and continued. Some divide them into intermittent and continued only; and subdivide the latter into those which continue unremittently, and which are therefore called “continent;” and into those which have remissions, and are called “remittent.” We may divide them in either of these ways. I shall first speak of “intermittent” fever.

<sup>a</sup> Besides a great number of plants, of various kinds, which are to be met with upon the island [Juan Fernandes], but which we were not botanists enough either to describe or attend to, we found there all the vegetables which are usually esteemed to be particularly adapted to the cure of those scorbutic disorders, which are contracted by salt diet and long voyages. For here we had great quantities of water-cresses and purslain, with excellent wild sorrel, and a vast profusion of turnips and Sicilian radishes. The two last, having some resemblance to each other, were confounded by our people under the name of “turnips.” We usually preferred the tops of the turnips to the roots, which were often stringy; though some of them were free from that exception, and remarkably good. These vegetables, with the fish and flesh we found here, were not only extremely grateful to our palates (after the long course of salt diet which we had been confined to), but were likewise of the most salutary consequence to our sick, in recovering and invigorating them; and of no mean service to us who were well, in destroying the lurking seeds of the scurvy; from which, perhaps, none of us were totally exempt; and in refreshing and restoring to us our wonted strength and activity.”—Anson’s “Voyage round the World,” Compiled by Richard Walter, M.A. Book 2; Chapter 1. (Smith’s “Standard Library” Edition; Page 36.)

## SECTION I.—SYMPTOMS AND VARIETIES.

*Pyrexia*.—All fevers, whether intermittent or continued, are characterized by those symptoms which I before spoke of,<sup>a</sup> when treating of inflammation, under the name of “pyrexia;”—that particular set of symptoms denominated “pyrexia.” In speaking of inflammation, I mentioned<sup>b</sup> that there are only two stages well marked in the pyrexia of that complaint,—cold and heat; but in an attack of real fever there are often three;—a *cold*, a *hot*, and a *sweating* stage. In intermittent fever, these are very distinctly marked. In *continued* fever we may have a shivering at the beginning; but then it will terminate in the course of the disease, and we shall have to treat long-continued heat. It is only towards the last, that there are any sweats; and frequently, there are none of a remarkable character; for there is often merely moisture of the skin, as the disease declines. But in *intermittent* fever there are usually three distinct stages;—a cold, a hot, and a sweating stage; the first of which is the cold stage.

*Cold Stage*.—When this stage is about to commence, the patient feels himself very weak and listless. He begins to yawn, gape, and stretch. He finds his mind less active; and his external senses are more or less dull. Sometimes there is even real stupor; but in all cases the patient's mind is very dull. He is unable to go on with what he is about; and even his external senses are impaired. There is also, at the same time, a great depression of spirits. Very soon a sensation of coldness is felt,—first of all in the back; and the patient will complain of chilliness, before others who touch him can perceive it. As soon as the cold stage has begun, the surface becomes pale and dry; and the mouth and fauces also become dry. Then the patient begins to tremble slightly. He becomes really cold;—the temperature falls perceptibly to others. He trembles more and more, and becomes colder, till he is in a state of downright shivering; and then his jaws chatter. The constriction of the skin at this time is so great, that it becomes rough; and, in common language, is called “goose's skin;” but in Latin, “cutis anserina.” Such is the shrinking, that rings which previously fitted very well will fall off. There is a sense of *creeping* and *shuddering* over the skin; the hairs of which stand on end; and this state is called “horripilatio.” The urine which is made at this time, is pale and scanty. Probably the same constriction of the secreting vessels of the kidneys takes place, which occasions the dryness of the surface of the body. It is the same constriction, I presume, of the secreting vessels, that gives rise to the dryness of the mouth and fauces, and also to the thirst. This is altogether a state of debility; and consequently the pulse is weak, and sometimes slow; and the breath is generally short;—from the accumulation of blood, I presume, in the internal parts. Sometimes the stomach is affected with vomiting. In a very intense cold stage, the face, hands, and feet, become blue; the fingers shrivelled, and the eyes sunk.

*Hot Stage*.—In the cold stage the blood has receded from the surface, and probably from all the small vessels; so that it has accumulated, in great quantity, in the large vessels of the interior. After this state has existed a certain period, of very various duration, the skin relaxes. It regains its warmth, colour, and sensibility; and the pulse becomes quick and fuller. The heat, the colour, and the sensibility of the skin, go on increasing; till at length they exceed their natural standard, and the pulse grows full and very rapid. Such is the excitement now, that not unfrequently the patient complains of headache; and even delirium occurs. The thirst, the dryness of the skin, and the deficiency of the urine continue;—probably because the extremities of the secreting vessels are still in a state of constriction; though the small vessels have become filled with blood. The urine, however, changes its character. From being pale and watery, it becomes high-coloured; but it is still clear. The breath becomes fuller; most probably from the blood getting

<sup>a</sup> See page 88.<sup>b</sup> See page 88.

into the small vessels; and the patient can take a deep inspiration. There is not that slow breathing, which there was at first; but still there is more or less oppression; for the heart is in violent action; and when that is the case, there is always a degree of dyspnœa. That state which is vulgarly called "fever," now takes place. If the disease intermit altogether, it is called "ague;" from the French word "*aigue*" ("sharp,"—"acute"). But the common people limit the word "*fever*" to the hot, or hot and sweating stages; and denominate only the cold stage "ague;"—so that it is common to hear one of the lower orders say that he has got "the ague and fever;" but "ague," properly speaking, includes the whole of the three stages. There is a passage in "*Macbeth*," where the poet says,—

—"The obscure bird  
Clamour'd the livelong night: some say the earth  
Was *feverous* and did *shake*,"<sup>a</sup>

It appears, therefore, that the word "*fever*" was applied, in those days, to the cold stage, as well as to the hot. There can be no doubt, that both the expressions "*pyrexia*" and "*fever*," though made by medical writers to include the whole stages, imply properly the hot only; as the former is derived from  $\pi\acute{\upsilon\rho}$ ,—"fire;" and the latter from "*ferveo*,"—"to be hot."

*Sweating Stage.*—After the hot stage, the skin at length becomes still softer. It also grows moist; and the moisture augments, till at last the person is in a profuse sweat. The same relaxation of the internal secreting vessels takes place; in consequence of which the thirst declines; the urine becomes copious; and the vessels let through so much substance, that it forms a lateritious<sup>b</sup> sediment.

After the sweating has continued an indefinite time, the pulse gradually grows slower; and the sweating and all the other symptoms diminish. The appetite, which is generally absent in all the three stages, now returns; and the patient is as well as though nothing had happened. If the disease last very long, the patient becomes shattered by it; but in general,—if the disease be not very severe, if there be no local affection, and if the patient have not laboured under it long,—when the paroxysm is over, he is much about the same as he was before.

There is great variety in the intensity of every one of the symptoms which I have mentioned. There is great variety in the relative intensity of the different stages; and great variety in the intensity of the whole disease together.

*Incidental Symptoms.*—This, however, is not all. There are, occasionally, incidental symptoms; such as tetanus, convulsions, fainting, violent delirium, and the appearance of petechiæ<sup>c</sup> on the skin. Some persons, while in the paroxysm, have been known to have their muscles rigid;—absolutely in a tetanic state. Others have been violently convulsed; fainting has occurred; and delirium, in the hot stage, is very common. Sir John Pringle mentions violent delirium, as the character of an epidemic intermittent which he saw prevail. He also mentions that, at Copenhagen, in 1652, petechiæ appeared in the hot stage of an intermittent which prevailed there. Bartholini gives an account of an epidemic, in which petechiæ appeared in the hot stage,—always disappearing afterwards. I have not seen the whole of these symptoms. Delirium, in the hot stage, is common enough; and in two cases I saw, in the cold stage, there was violent clenching of the hands,—so that the fingers and thumbs were drawn together in the most violent manner, and continued so until the cold stage was over.

*Periodical Recurrence.*—These stages may all take place in the course of one day, and never return; and then the disease has been called "*ephemera*;"—"a disease of a day's duration." But, for the most part, these stages return not only regularly, but periodically; so that you do not have ephemeral ague, but intermittent fever. The intermission between two paroxysms, is usually part of one day, at least; or it may be a whole day, or two days. By "*day*," in medicine, we

<sup>a</sup> Act 2; Scene 3.

<sup>b</sup> From "later," "*lateris*," a brick.

<sup>c</sup> From the Italian "*petechio*," a flea-bite.

mean day and night;—the twenty-four hours. Beyond two days, the intermission is rarely regular. If the intermission be only part of a day,—that is to say, if the attack returns every day,—the fever is called “quotidian.” If there be an intermission of a *whole* day,—so that the patient has an attack every *other* day,—it is called “tertian.” It assumes this name, because the first day is counted as well as the third. The day on which a person is attacked, is the first; the day of intermission, the second; and the day of the second attack, the third. It is, therefore, called “tertian.” If the intermission extend two days,—so that the patient shall have a fit on Monday, none on Tuesday, none on Wednesday, but one again on Thursday,—then it is called “quartan.” The day of the paroxysm constitutes the first; then follow the two days of intermission,—making three days; and then, on the fourth, we have another paroxysm. These are the most common forms of the types of intermittent fever; and, in London, the quotidian and tertian are far more frequently seen than the quartan.

But the intermission may be still longer; so that we have, not a quartan, but a quintan, a sextan, a septiman, or even a deciman. In the last there is an interval of nine days; and the first day, being counted, makes up the ten. I heard a gentleman observe, that he saw a septiman take place for three weeks; that is to say, the person had a paroxysm after an interval of six days, occurring on the seventh day, regularly for three weeks. In 1827, I myself had a patient in St. Thomas's Hospital, with a septiman. He regularly had his disease, after an interval of six days. During the same year I had another patient, who had an interval always of four days; so that his disease was a quintan. I once treated a double octavan. A man had a paroxysm every Sunday and Thursday;—the Sunday paroxysm being at one hour; and the Thursday paroxysm always at another. When they extend to these periods,—when they are more than a quartan,—when the intermission is longer than two days, the disease is called “erratica;”—it wanders out of the usual regular course. The epithet “*erratica*” is also given to an ague which observes no regular period;—which at one time is quartan, at the next, quintan, &c. The term “*erratic*” is employed by authors in both these senses.

*Double Tertian.*—These are, for the most part, all the varieties which it is necessary to recollect; but, as a matter of curiosity, I may mention that the disease has sometimes other types. Sometimes we have more than one paroxysm in a day,—more than a quotidian; and I heard a gentleman say, that he witnessed a case in which there were four paroxysms daily. I never did. But it is very common indeed, to see what is called “a *double tertian*”; in which there is a paroxysm every day; but where the paroxysms occur two days in succession, yet do not belong to each other. For example: suppose a patient has an attack every day in the week; but the paroxysm on Monday is at eight o'clock in the morning, and the paroxysm on Tuesday at four in the afternoon; while the paroxysm on Wednesday is at eight o'clock in the morning,—like the paroxysm on Monday; so that the paroxysms on Monday and Wednesday agree; whereas the paroxysm on Thursday is at four o'clock in the afternoon;—the same hour as the Tuesday paroxysm. Now this appears a *quotidian*, because it occurs every day; but it is, in reality, a *double tertian*; for it is as if the patient had a tertian which came on every Monday and Wednesday; and another which came on every Tuesday and Thursday; and, inasmuch as the paroxysms which occur every other day agree, it is called not “a *quotidian*,” but “a *double tertian*” (in Latin “*tertiana duplex*.”) But it will sometimes happen, that there are two fits on the day of attack, and none on the following day. Supposing the disease come on every other day (as, for instance, Monday and Wednesday), but that, on each of those days, there are two attacks; it is then called “a *duplicate tertian*” (“*tertiana duplicata*.”) That is the difference between “*tertiana duplex*,” and “*tertiana duplicata*.”

Respecting the double tertian,—the one which comes on every Monday and Wednesday, for instance, and every Tuesday and Thursday, but at different hours,—we sometimes find scarcely any intermission between the Monday's and the Tuesday's paroxysm; while the intermission between the Tuesday and Wednesday

paroxysm is distinct enough; or, *vice versa*, that the one is hardly over when the other begins; and it is then called "*semi-tertian*,"—"half-tertian" (*ἡμιτερτiana*). The paroxysms are brought so near, that it is almost remittent fever; and it is scarcely worth while to call it any thing else than "remittent." Though the interval between the attacks on the first and second day is very short, yet the intermission between the second and third is much longer. We may, however, not only have a *double tertian*;—one on Monday and one on Wednesday at a certain hour, and again on Tuesday and Thursday at another hour; but on Monday there may be two fits, and on Wednesday two fits; and then this is called "*a triple tertian*."

We may also have a "*quartana duplex*" ("*double quartan*;" )—there being an additional paroxysm on the first day of the intermission, at its own hour; and "*a quartana duplicata*" ("*duplicate quartan*;" )—two paroxysms on the day of attack; and also "*a tripled quartan*;"—three paroxysms on the day of attack. The observations I have made, are sufficient for all practical purposes; and I only wish it to be remembered, that these extraordinary deviations do sometimes take place.

*Duration of the Paroxysm.*—A paroxysm of intermittent fever, including the three stages, is generally finished in eighteen hours. It is a rare occurrence for it to last longer than that period. Dr. Good, however, quotes an author, who stated that he saw a paroxysm which lasted exactly *one minute*. How the stages were divided I do not know. What was the severity of the cold stage, it is impossible to conceive; but I should think, that when each of these stages was over, the man might have doubted whether he had been ill or not. But authors may be quoted for any thing.

*Time at which it Occurs.*—The paroxysm of ague is said (like almost all fevers, indeed) more frequently to begin in the day than in the night. As a general rule it may be stated, that the paroxysms commence between eight o'clock in the morning, and the same hour in the evening. Of course there are numerous exceptions; but, in the majority of cases, the paroxysm begins in the day. It is mentioned by authors, that a quotidian usually has its paroxysms in the morning, a tertian at noon, and a quartan in the afternoon. I believe there is some truth in the observation, that a quartan generally begins late in the day; but tertians very frequently come on in the afternoon, quartans at noon, and quotidians in the evening. It is said, likewise, that a quotidian has the shortest *cold stage*, but the longest *paroxysm* altogether; that a tertian has a longer *cold stage*, but altogether a shorter paroxysm; whereas a quartan has a still longer *cold stage*, but nevertheless a shorter *paroxysm* than either of the others. But for these particulars there is no universal rule.

*The Body sometimes only Partially Affected.*—Some very curious cases of paroxysms affecting only a part of the body, have been recorded by authors entitled to credit. There is one case mentioned, in which a vertical half of the body suffered an attack of the ague; and during the cold fit, the other half became convulsed. What is still more singular,—the same half was not always similarly affected, but the symptoms changed sides. There is likewise a case mentioned, where paroxysms of ague affected one half of the body horizontally. In some cases it has only affected half the head; and Dr. Macculloch says that a paroxysm may affect one limb only. Now these facts are not at all insulated. They are perfectly analogous to many others which are occasionally observed in the human body. Epilepsy will sometimes affect only one half of the body; nay, sometimes it will affect only one limb. Catalepsy will do the same; and paralysis does this so continually, that one of the established forms of palsy, is hemiplegia; and another is paraplegia. Dr. Abercrombie, in his work on the Pathology of the Brain,<sup>a</sup> says that a friend of his, when in exercise, only sweats in a vertical half of the body;—that there is a line upon the forehead, perfectly distinguishing the sweating from the dry side; but that if he takes very violent exercise indeed, then the dry side is

<sup>a</sup> "Pathological and Practical Researches on Diseases of the Brain and the Spinal Cord; by John Abercrombie, M. D."

at last forced to perspire a little, like the other. In the work of Andral<sup>a</sup> (another modern writer), will be found instances in which sweating took place in one half of the body only. In some of these cases it was a vertical, and in others a horizontal half. We find a case mentioned by Dr. Falconer, in which a child became pale and emaciated in one half of the body only.

*Changes in the Type.*—Intermittent fevers, during their progress, frequently change their type. From tertian, they will frequently become quotidian; from quotidian, tertian; and from either of these, quartan; while from quartan, again, they will become either of the former. Sometimes they will change their type once; sometimes more than once; and sometimes they will continue changing,—so as it observes no rule at all; and then, as I have already said,<sup>b</sup> they are called “erratic.” Another variety is, that they will not change their types;—they will still remain quotidian, tertian, or quartan; but they will change the hour of their attack. Instead of beginning at the same hour, they will begin later and later, or the reverse; and sometimes they will begin with such irregularity, that a patient never knows when to expect them. Sometimes they will be very irregular at first, and then at last they will grow regular;—seeming only to make up their mind, after a time, how they shall go on. At other times, they will grow milder only. It is a general rule that the paroxysms grow later and later as they grow milder. As the paroxysms become more severe,—more intense, and the disease gets worse, they generally come on earlier and earlier; but when the paroxysm grows later and later, and at the same time milder and milder, it at last degenerates into nothing more than a little chilliness, a little heat, a little sweating, or a little of all combined. It is very common, at last, for the paroxysm to show itself only a little at a certain time of the day; or there is only a little sweating, or a little chilliness. These diseases occur chiefly in spring and autumn. Authors therefore frequently write of *vernal* and *autumnal*, ague. The quartans usually take place in autumn;—that is to say, there are more quartans among *autumnal*, than among *vernal* agues.

*Variety in the Paroxysms.*—Although agues have generally these three stages, the paroxysms are sometimes imperfect, even before the disease has much declined. I have often seen and cured an ague, in which the cold stage took place, but was never succeeded either by the hot or sweating stage. Sometimes the hot stage alone will come on;—not being preceded by the cold stage. A paroxysm is generally terminated by the sweating stage; but sometimes there will be no sweating at all. We may have either of the three stages alone. This is worthy of remark; and it is an undoubted fact; for I have witnessed it, over and over again. Cullen says that the cold stage is necessary to the others. He considers that the cold stage excites the “*vis medicatrix naturæ*”;—that, to get rid of the *cold* stage, nature bestirs herself, and brings on the *hot*, and then the *sweating* stage. But this is a fallacy; for I know we may have the hot stage, without any cold preceding it; and that we may have the cold stage, without any subsequent hot stage. Sometimes there is no regular paroxysm at all; but patients with ague will have, at various periods, a general chilliness, with great depression of spirits;—so that they will cry, yawn, stretch, and often be even a little silly, and have a number of odd feelings. Now this state of things is well known by the lower orders; and is called by them, very significantly, “the *dumb* or *dead* ague;”—an ague which is not at all lively, or does not speak or show itself in an open and manly manner. It is, however, to be treated exactly like all other forms of the complaint.

I have mentioned, respecting the variety in the paroxysms, that sometimes there will be one stage alone without the others; but one author tells us that he saw all the stages reversed; that the disease began with *sweating*; then the *hot* stage came on; and the paroxysm was closed by the *cold* stage. Before this disease is fully formed, the attack is sometimes preceded by headache, by pains in

<sup>a</sup> “Clinique Medicale, ou Choix d’Observations recueillies a l’Hopital de la Charité, par G. Andral.” This work, which is a vast repository of valuable pathological facts, has recently been translated by Dr. Spillan.

<sup>b</sup> See Page 236.

the nerves (neuralgia), by vomiting, by general indisposition; and all this may last for a longer or shorter time. These symptoms may cease on the appearance of the disease; or they may continue, more or less, when the affection is established. Even continued fever has preceded ague.

*Duration of Ague.*—The duration of ague is various. It may be ephemeral,—consisting of one paroxysm; or it may last for many years;—at least, it did so before we could cure it so effectually as we can now. One case is said to have lasted eight-and-forty years. Lommius, who wrote in beautiful Latin, mentions a case which lasted twenty years. One unfortunate fellow (Valescus of Tarenta) is said to have had it all his life. Dr. Gregory<sup>a</sup> said that he saw one case which had lasted four years. On the other hand, Dr. Mason Good<sup>b</sup> quotes Senac for a case, in which the disease destroyed life the moment it began. When it proves fatal, Sydenham says it is in the cold stage; because, when the hot stage comes on, nature is getting the better of the disease; and that a patient cannot die from it if nature be recovering, as is the case in the hot stage. But the truth is, that it *will* kill in the hot stage. In hotter climates than our own, there is great congestion of the internal parts of the head; and persons will fall into a state of coma, as they sometimes do here in the first stage. I have known some people have it every spring for many years. Although we have never seen people that have it regularly all the year round, yet most of us have seen individuals who have the disease regularly once a-year. Respecting its duration, however, quartans are said to last the longest. Tertians and quotidians are more like an acute disease; but the quartan, coming on after an intermission of two days, partakes more of the nature of a chronic affection; and being chronic in its *character*, so really it is chronic in its *duration*. Certainly it is the quartan that, in general, lasts longer than the others; and it is generally more difficult to cure. On the same principle, again, it is said that a tertian, left to itself, lasts longer than a quotidian.

*It affects every Period of Life.*—Ague affects all ages. It is seen in young children even at the breast; and I had under my care, for this affection, a man about eighty years of age. It is said to affect children *earlier* than when at the breast;—to affect them before they are born. Cases are mentioned, not only in which the children had a paroxysm of ague the very moment that they came into the world, but in which a child had the disease before it was born. In Dr. Russell's "History of Aleppo," there is an account of a woman who had a tertian ague. This woman was with child, and she shook every other day; but the child within her she felt shaking regularly on the day when she was disposed to be quiet. She shook, for example, on the Monday and Wednesday; but the little one shook on the Tuesday and Thursday;—so that *she* had *one* tertian, and the *child* had *another*. If it had not been for this diversity, she could not have ascertained that the fœtus had an ague, nor could the doctors. What farther proves that the child had a different ague from the mother, is that Peruvian bark was given to the latter, and that it cured both her and the child; but as the child was so much younger, I suppose the bark had more effect upon it: for it was cured one paroxysm before the mother. A gentleman informed me, that he saw a similar case at a dispensary in London. The woman came shaking with ague; and the child within her shook like herself, only at a different time. I suppose there is no doubt of the truth of the case related by Dr. Russell. There is no question about children having had the small-pox in the womb. Mr. Abernethy used to mention the case of a child that had the *disease*, though not the peculiar *symptom* of hooping-cough, before it was born. It was affected by the contagion; though, for want of breath, it could not hoop before birth; but it embraced the very earliest opportunity it had of doing so;—so that the first thing it did was to *hoop*, instead of *cry*.

*It is liable to Return.*—When this disease has once occurred, it is very liable to return, from common causes. Cold, wet, and (in this country) the east wind par-

<sup>a</sup> Dr. James Gregory, author of the "Conspectus Medicinæ Theoreticæ."

<sup>b</sup> "Study of Medicine;" Class 3; Order 1; Genius 2; Species 5.

ticularly, have a tendency to bring it back. Whether it will recur spontaneously I do not know. Whether, without cold and moisture, and without an east wind, or some wind charged with malaria, it will return, I cannot say; but certainly, when a person has once laboured under it, frequently the slightest cause will bring it back. Dr. Gregory<sup>a</sup> saw two persons, in whom ague returned, from some common cause, after having been absent forty-seven years. Dr. Gregory also stated that it had been known to recur, after a lapse of years, at the very day and hour on which it originally began.

*It Modifies the Character of other Affections.*—The existence of this disease gives an intermittent, or remittent tendency, to many other affections that may be present. Suppose a person has a disease, and that he is then attacked by ague;—the first disease will have a tendency to blend with the ague; so that he will have remissions, if not *intermissions* of it. When ague prevails epidemically, though persons may be exempt from any other disease which they may have at that period, it will show a tendency to an intermittent or remittent character. This, however, is chiefly seen in fever. When ague prevails, or persons are exposed to the cause of ague, continued fever has a tendency to put on the remittent form; and remittent fever appears to be a combination of continued and intermittent fever.

*Complications of Ague.*—Ague is very frequently followed by rheumatism. I am not acquainted with a more frequent occurrence, than that of ague being followed by severe rheumatic pains in the extremities, or in the head. Occasionally it will alternate with rheumatism; so that the rheumatism shall cease, and the ague return, and *vice versâ*. Dr. Gregory<sup>a</sup> used to mention, that he saw ague alternate with epistaxis; and in another case he saw it alternate with hæmaturia,—bleeding from the urinary passages; which bleeding, however, ceased at last; and then the ague returned, and was followed by paralysis. He used also to mention, that he saw two cases of ague continue four years; at the end of which they were cured by bark; but periodical delirium came on in its stead.

## SECTION II.—COMPLICATIONS AND EFFECTS.

*Local Inflammation.*—Ague is very often attended by local inflammation; sometimes by inflammatory pains of the head; sometimes by inflammatory affections of the chest, and likewise of the abdomen;—particularly gastritis and hepatitis. In autumn, and in hot climates, it is the abdominal viscera that suffer the most severely; and ague is likewise very frequently attended (when there is no inflammation of these parts) with bilious vomiting and purging; and even by jaundice and dysentery. In some places (Zealand, for instance) Sir John Pringle mentions that ague is called “gall-fever.” It is on account of the great irritation of the liver that takes place, and the abundant secretion of bile, that aguish diseases is thus called.

*Congestion and Effusion.*—After death during intermittent fever, we often find congestion and effusion in the head, chest, or abdomen. The mucous surface of the alimentary canal, is likewise in a state of great congestion; and the liver contains a large quantity of bile. When this disease proves fatal, it frequently does so by great internal congestion; whence there is fulness of all the blood-vessels of the head, chest, stomach, and intestines; and a large quantity of bile on the liver. When the disease has continued for a considerable time, we have various organic affections;—such as dropsies, and other diseases which I shall mention hereafter. But when a patient dies in a paroxysm, or dies after the disease has existed only for a short time, we find decided marks of internal congestion.

*Enlargement of the Spleen.*—The chronic form of the disease, is very frequently attended by other affections; and frequently, after ague has ceased, other diseases make their appearance. It is very common, for example, when ague has continued any time, for the spleen to become enlarged. So common is this, in some places,

<sup>a</sup> See Note to Page 239.

that the tumour is called (by the vulgar) "ague-cake." The tumour thus formed by the spleen, occupies the left hypochondrium; or, perhaps, the whole left half of the abdomen. Dr. Cleghorn, who wrote a very excellent work on the diseases of Minorca, mentions having seen a spleen, after ague, which weighed eighty ounces. Dr. Gregory<sup>a</sup> used to speak of one that weighed twelve pounds. We frequently see this enlargement of the spleen in the case of infants. I have seen many enormously large spleens, in infants who had been the subjects of ague. We frequently, likewise, see enlargement of the liver and jaundice. Enlargement, both of the spleen and the liver, is common; but particularly of the former. In the case of the spleen, the patient is for the most part pale;—he falls into a state of anæmia (bloodlessness); while, in the case of the liver, he becomes more or less jaundiced.

*Ascites and Anasarca.*—When this affection has existed for any length of time, it is common also to see ascites, as well as enlargement of the spleen. Very frequently there will be anasarca, *as well as* ascites; and not unfrequently *without* any ascites, there will be anasarca; and these affections generally remain, for a longer or shorter time, after the ague has ceased. They will occasionally come on while the ague exists; and occasionally not till it has ceased; and, in the former case, they are all the worse for the continuance of the ague. It was formerly imagined, that these affections arose from the ague being stopped; but this I am convinced is a mistake. Persons will have them, who still have ague very violently; and these complaints are the worse for the ague. Patients will bear them much better if we cure the ague. The ague shatters the constitution; and renders it a more easy prey to any visceral disease that may exist. I do not believe these affections are the effect of ague. On the contrary, I am satisfied they are the result of the same cause which produces ague, and of which I shall presently speak; for I have seen people labour under enlargement of the liver, enlargement of the spleen, and dropsy of great intensity, who had but one fit of ague; and a fit which bore no proportion to the severity of these other complaints. It appears to me, that the same cause which produces the ague,—a poisonous exhalation,—produces likewise these various effects; and, indeed, they render the ague more obstinate. It is sometimes almost impossible, or quite so, to cure an ague while these affections exist; but if we remedy them as well as we can,—by mercury, bleeding, purging, and the usual remedies of chronic inflammation,—we shall frequently cure the ague without any trouble. If they arose from the ague being *suppressed*, we should not have them while the ague *continued*; and if they depended on the *ague*, and not on the *cause* of the ague, they ought to bear some proportion to its degree and continuance; but they appear to bear a proportion, in some measure, to the continuance and intensity of the *cause* of the ague. Still the continuance of ague, by debilitating the system, does make them worse.

*Idiocy.*—Another circumstance, mentioned by some authors as an effect of ague (or, perhaps I should say, of the *cause* of ague), is idiocy. The faculties of the mind frequently become impaired, by a long exposure to the cause of ague. Sydenham mentions a degree of idiocy, or (at least) of impairment of the mental faculties, which he calls "amentia quartana" ("quartan faculty"). There can be no doubt that the continuance of ague *increases* such affections, by debilitating the constitution; but I do not believe that ague *gives rise* to them; but that they proceed from the same cause which produces ague.

*Local Complications dependent on the Time of Year.*—Vernal, or spring intermittents (those which make their attack between the winter and the summer solstice) are chiefly attended by affections of the chest;—that being the period at which affections of the chest are most prevalent. The autumnal intermittents (those which take place between summer and the winter) are particularly attended by abdominal symptoms;—by inflammation, for instance;—and sometimes by intense bilious vomiting, purging, and jaundice. At this time of the year, too, ague has a

<sup>a</sup> See Note to Page 239.

great tendency to become continued fever;—that is to say, the excitement is disposed, not to *cease*, but only to *remit*. When the autumnal intermittents prevail, we have as many remittent fevers as agues; and some of these become continued. This conjunction most probably arises from the fact, that the causes of these various local excitements, and also of continued fever, coexist with the cause of ague. Without any ague at all, we are all disposed to affections of the bowels, and of the stomach and liver, in hot seasons of the year; and if, therefore, the causes of ague are joined with the causes of these common affections, ague will, of course, be accompanied by these other diseases. Still it is possible that the cause of ague may be modified; so as to produce peculiar effects at this season.

*Sometimes Stops other Diseases.*—Sometimes ague, so far from being accompanied by other diseases, actually puts a stop to diseases which had previously existed. Dr. Gregory<sup>a</sup> used to mention, that he saw palpitation cured by ague; that the man lived afterwards for many years; and died free from the palpitation, under which he had suffered till the ague seized him. Dr. Fordyce mentions, that he has seen ague cure many diseases. In fact, ague has been thought so capital a thing, that some writers contend it never should be cured; and a proverb once prevailed that—

“An ague in spring,  
Is fit for a king;”—

not, however, for a *subject*, I think. Boerhaave says, in his Aphorisms,<sup>b</sup> that it disposes to longevity, and clears the body from inveterate diseases. His words are,—“*Cæterum (febres intermittentes) nisi malignæ, corpus ad longævitatē dispōnunt; et depurant ab inveteratis malis.*”<sup>c</sup>

*Aggravates other Coexistent Diseases.*—There is no doubt, however, that agues shatter the constitution. They shorten life; they may be speedily fatal; and if any other disease exist at the time, they for the most part aggravate it. Dr. Macculloch believes, that when they appear beneficial, it is generally not by curing other diseases, but merely by their assuming a regular type. Ague, as I mentioned before,<sup>d</sup> is sometimes obscure,—does not declare itself fully; and is then called “*dumb* or *dead* ague;” and, in these circumstances, we sometimes have extraordinary symptoms, which will disappear if the ague come on in a regular, straightforward style. It is therefore mentioned by Dr. Macculloch, and appears very plausible, that when benefit appears to arise from ague, it is from the disease having existed previously, but in so strange a manner, as to produce all sorts of symptoms; and from its having all at once become regular. It cannot be one thing and another thing at the same time; but when it becomes regular, then, for the first time, a person thinks he has got an ague, and has lost some other disease.

*Effects on the Adipose Tissue.*—The continuance of ague usually causes emaciation of the body, unless it produce hepatic, or splenic disease, and dropsy; and then the body will look bloated; but still it is pale, and evidently greatly diseased. It is even said that (in some parts of Flanders, especially) ague has a tendency to produce obesity; and sometimes very rapidly; but I imagine that the fat cannot be what people call “*good* fat.” There is a sort of bloated blubbery fatness; and when it is remarked that such a person has got fat, people will shake their head, and say—“It is not *good* fat.”<sup>e</sup> It is said that this obesity will occur there, whether the disease has been acute or is chronic; and when there is no suspicion whatever of organic disease. It is said, too, that if the disease return there, or if the seasons be very unhealthy, and a patient becomes emaciated, the obesity returns when all this is over. Many fat Dutchmen live in places where malaria prevails; but still they do not look healthy. The ill effects of the disease are so manifest, that no one who has an ague, ought to be much displeased with the doctor for curing him

<sup>a</sup> See Note to Page 239.

<sup>b</sup> Aphorism, 754.

<sup>c</sup> “Intermittent fevers, unless of a malignant description, dispose the body to longevity, and clear it from obstinate disorders.”

<sup>d</sup> See Page 238.

<sup>e</sup> See Dr. Macculloch’s “Malaria,” Page 430.

of it. Oliver Cromwell,<sup>a</sup> and James the First, are said to have died of ague, caught in London. Dr. Caius says, that so fatal was ague in London, in the year 1558, that the living could hardly bury the dead. Bishop Burnett says, in his "History of the Reformation," that so universal was it in London, and so contagious (though that was a mistake), that it raged like the plague.<sup>b</sup> Sydenham and Morton both tell us, that from 1661 to 1665 it was the most fatal disease in London. In our unfortunate expedition to Walcheren, in no more than five weeks,—that is to say, during the last week of September, and the whole of October,—our effective force was reduced by ague, or by remittent fever,—agueish disease, to one-third; and ten thousand men died of what was called "Walcheren fever," which was neither more nor less than an *agueish* fever.<sup>c</sup>

*Does it Antagonize other Diseases?*—If it should so happen that a much worse disease than ague is arrested by its occurrence, we might allow the latter to go on; but even then I should be inclined to stop the ague gradually; and to use, at the same time, the remedies calculated to remove the other disease. For example: ague, I suppose, is preferable to phthisis; and if a patient were actually in a state of consumption, and the consumptive symptoms ceased on the occurrence of ague, one might be disposed only to *mitigate* the ague, but not altogether to *cure* it. However, I never met with any of these cases. A very eminent man, Dr. Wells (one of my predecessors in St. Thomas's Hospital), fancied he had good ground for suspecting, that phthisis and ague were opposite;—so that where ague prevailed, there was no phthisis; and *vice versâ*. It really appears that there is something in this;—that ague does lessen the tendency to phthisis; but still the matter is not so important as Dr. Wells imagined. The opposition of one disease to the other, is nothing like what he fancied it to be. The question is argued by Dr. Southley, in a book on Consumption;<sup>d</sup> in which he has taken great pains to collect documents from aguish parts; and proves that there is phthisis enough in those parts. I have seen several persons die of phthisis, while they had more or less ague. Some have carried Dr. Wells's opinion so far, as to send a patient, who was half dead with phthisis, to stand in a ditch at night;—in order to catch an ague.

*Effect on the Countenance.*—One of the effects of ague is shown in the countenance. The face in ague, and long after, is often very peculiar. It is of a dirty straw-colour; and is so well characterized, that it has been called "*agueish* face." The face is not yellow, nor of the colour of *clean* straw; but presents a sort of *dirty* straw-coloured look. Without the occurrence of ague, the mere residence in an aguish place gives the same hue;—so that it is the effect of the *cause* of ague.

### SECTION III.—CAUSES.

#### *a. Predisposing Causes.*

*Bad Health.*—I shall now speak of the *causes* of ague; and, among the predisposing, must be first mentioned bad health. If a person be out of health in any respect, he is more likely to be affected by the causes of ague;—just as is the case with respect to all other diseases. A general weakness of body, independently of the presence of any particular disease, must have the same effect. High health, in general, is certainly one of the best safeguards against it. The father<sup>e</sup> of the late

<sup>a</sup> See Dr. Macculloch's "Malaria," Page 4.

<sup>b</sup> See Dr. Macculloch's "Malaria," Page 128.

<sup>c</sup> It is said that ten thousand men were lost by Walcheren. How far the campaign itself was lost through the same cause, it is not needful to ask.—"Malaria: by John Macculloch, M. D." Page 227.

<sup>d</sup> "Observations on Pulmonary Consumption; by Henry Herbert Southey, M. D."

<sup>e</sup> The physician who wrote two very excellent works, distinguished by refined ideas and a high tone of moral sentiment, entitled,—"*A Father's Legacy to his Daughters,*" and "*The Duties of a Physician.*"

Dr. Gregory,<sup>a</sup>—the latter was one of my preceptors,—used to mention, that when he was a student at Leyden,—for then, if persons wished to get a good medical education, they were obliged to go to the Continent,—there were twenty-four students who always dined together, and were very much in each other's society. Twenty-three of them regularly, every day, drank a bottle of claret each; but one confined himself to water. The twenty-three escaped; while the poor water-drinker caught an intense ague. This strikingly exemplifies the advantage of keeping up the vigour of the body, when persons live in an unhealthy situation. It was *claret* which they drank,—not *port*; but that was quite sufficient to keep up a degree of excitement of body, and strength of mind, which enabled them to resist the disease.

The good effects of wine, in keeping up the strength against this disease, are also shown in the fact, that people find it indispensable in the marshy parts of France.<sup>b</sup> They cannot resist ague there, unless they drink wine. Sir John Pringle mentions, that wine and full diet are the best safeguards against it.<sup>b</sup> The Dutch are in the habit of exciting themselves, by taking spirits, before they go out in the morning;<sup>c</sup> and it is highly necessary,—exposed as they are to the exhalations of their putrid ditches.

*Depression of Spirits.*—Depression of spirits will have just the same effect as too low a scale of living. Any thing which lowers the body at large, will have the same effect;—whether it be over-exertion of the body, or of the brain or mind (whichever we choose to say); or the want of good food and clothing, or of pleasurable excitement of mind; or the presence of any thing which can depress the spirits. It is said, that the effects of the mind were seen at Walcheren; and probably they were;—owing to the following circumstance:—When the men arrived there, all full of the hope of military glory, they for some weeks continued healthy; but at last, when they saw that there was nothing to be done,—that the expedition would fail, they soon became the victims of disease. It is to be considered, however, that latterly they had much greater fatigue to go through; and the longer they remained there, the more they were exposed to the morbid cause of ague; but still, when they lost all mental excitement, by the failure of the hope of what is stupidly called “military glory,” they nearly all fell victims to the disease.

*Predisposition from Age or Sex.*—Though all ages appear liable to the disease, infancy and extreme age are less liable to it, than the middle period of life. Certainly the greater number of persons whom I see labouring under ague, are neither infants, nor those much advanced in years. It is to be remembered, however, that persons in the extremes of age, are much less exposed to the *cause* of ague than others. Women too, less frequently have ague than men; but I should think this arises, not from the female constitution being less liable to it, but because (from spending a greater portion of time at home) females are less exposed than men to its cause. Sir Gilbert Blane states that, during the ten years he was physician to St. Thomas's Hospital, he had one hundred and ninety-two cases of ague; only thirty-three of which were in females.<sup>d</sup> I made an estimate of my cases of ague at St. Thomas's, during a period of five years; and found that I had one hundred and forty-two cases, of which only twenty-three occurred in women.

*Liability from going into an Aguish District.*—It would appear that persons who have not been exposed to the cause of ague, are more liable to suffer, when by chance they are exposed; for those who have formerly lived among agues, if exposed at any subsequent period, will often escape, while the others suffer. Hence it is said that some farmers, in aguish parts, have made fortunes by marrying a succession of wives from healthy districts.<sup>e</sup> Coming fresh upon an aguish part,

<sup>a</sup> See Note to Page 239.

<sup>b</sup> See Dr. Macculloch's “Malaria,” Page 283.

<sup>c</sup> See Dr. Macculloch's “Malaria,” Page 281.

<sup>d</sup> See his paper on “Intermittent Fevers,” in the third volume of the “Medico-Chirurgical Transactions,” Page 32.

<sup>e</sup> Dr. Macculloch, in quoting this opinion, intimates that the practice is not confined to England, but extends to France:—“It has sometimes been known, that one man has married three, four, or even five wives;—the tale being told in Bresse, (if I am not mistaken,) of three

the wives have been taken hold of by the malaria; and a good, *kind* husband has been enabled to look out for a second, and a third, to *love*. However, although persons may become habituated to it (as they may to any thing else), yet it more or less injures the constitution;—so that those who live in aguish parts, unless they are well fed and in good spirits, suffer more or less. They seem to be gradually poisoned by the causes of ague; although these may not have been sufficient to excite ague itself.

### b. *Exciting Cause.*

The *exciting* cause of ague,—the true indispensable cause of it, I believe to be an exhalation from decaying vegetable matter;—what is sometimes called “phyto-septic” matter,” “vegeto-putrescent matter,” “miasm,”<sup>b</sup> “marsh-miasmata,” or “malaria.”<sup>c</sup> However, “*marsh-miasmata*” is an improper expression; for though it will come from a marsh, we may have it without the existence of any marsh at all. It is said that the causes of ague were not known to Sydenham, or to Stahl; and that they were first assigned by an Italian author (Lancisi), in 1717. It is said that neither Boerhaave (who wrote in 1747), nor Baron van Swieten (who wrote a few years afterwards), was aware of the cause of ague. Dr. Cullen, however, from extensive reading, satisfied himself that there was but one real cause of ague; and that it was the exhalation which I have now mentioned. The ancients were quite aware that marshy districts were exceedingly unhealthy. The least acquaintance with the classics, will furnish us with lines enough to prove this.<sup>d</sup>

The reasons for ascribing aguish remittent or intermittent fevers, to these exhalations from vegetable matter in a state of decomposition, are the following:—1. The disease prevails in the neighbourhood of marshes. 2. It declines in proportion as marshes are drained. 3. It rarely appears in any one, who has not been evidently exposed to the exhalations of decomposing vegetable matter.<sup>e</sup> Every one has heard of the ague of the low countries,—of Flanders; every one has heard of the aguish fevers of the banks of the Ganges; every one has heard of the ague of the fens of Lincolnshire, the hundreds of Essex, and the lower parts of Kent. I mentioned that the disease is not by any means confined to marshes. It springs up around marshes, where persons are exposed to their exhalations; but every spot which contains decomposing vegetable matter, may excite the disease. On this account, I should prefer the term “*malaria*” (which, indeed, is now generally used) to that of “*marsh-miasmata*.”

brothers who had married (between them) fifteen women.” See Pages 447 and 448 of his “*Malaria*.”

<sup>a</sup> From *φυτον*, a herb; and *σνπω*, to putrefy.

<sup>b</sup> From *μιασμο*, to infect.

<sup>c</sup> The Italian name for an intermittent fever, which is endemic in the neighbourhood of Rome.

<sup>d</sup> By the testimonies of Solinus and Dionysius of Halicarnassus it is proved that the first settlers [at Rome] were obliged to abandon the Palatine Mounts, in consequence of the pernicious exhalations of the Velabrum; and we are also informed by Columella, that the land near Tusculum, cultivated by Attilius Regulus, was pestilential.—We find, from Plutarch, that noted periods of sickness occurred in the time of Romulus, and in that of Numa; and Livy says that, in the short period of a hundred and seventy-three years, there occurred at Rome, or in the surrounding country, no less than nineteen distinct plagues; some of which lasted for two or three years.—Cato mentions places, where it was impossible to live on account of the badness of the air; Livy speaks of tertians and quartans; and Varro advises the proprietor of an unhealthy farm to sell it at any price; or, in case that was impracticable, to abandon it.—It is related, by historians, that armies were often obliged to quit their encampments near marshes, on account of diseases.—That the city and the country also were unhealthy, is a fact so very familiar, that it is superfluous to do more than remind the reader of the names of Strabo, Martial, Horace, Seneca, Galen, and others.—“*Malaria*; by John Macculloch, M. D.” Pages 169 to 173.

<sup>e</sup> Dr. Fletcher attributes marsh-miasmata to exhalations, not from *decomposed*, but from *discased*, vegetables. See the “London Medical and Surgical Journal,” for June 3, 1837. (Volume 1, 1837-8; No. 9; Page 254.)

*Moisture alone is Insufficient.*—It is not mere moisture which produces the disease; for there is no ague, however wet the weather may be, till swampy land is approached, or exhalations arise from a swampy part. No drenching by rain, will produce it; unless a person has had ague before, or has been exposed to malaria. But when a person has once had ague, taking cold (whether there be moisture or not) may re-excite it; or may render the system susceptible of the effects of malaria, which it had resisted before. In the thick fogs on the banks of Newfoundland, people never experience ague. The waters there come from the Gulf of Mexico; and are called “the gulf-stream.” They are from six to ten degrees higher in temperature, than Newfoundland; in consequence of which the vapour which passes from the water, is immediately condensed. There is, therefore, a constant fog; so that the fishermen who reside on the great bank, are six months employed in fogs so great, that they can hardly see from one end of the ship to the other. But though they are thus constantly enveloped in moisture, they are never known to have the ague. There is more rain in the western, than in the eastern parts of England; and yet the inhabitants are not proportionately unhealthy. On the contrary, it is on the eastern side that ague particularly prevails;—as I shall mention hereafter. So much with respect to mere moisture.

*Exhalations.*—With regard to exhalations, I may mention that Minorca, though it has a rocky bottom, and no marshes, is nevertheless subject to ague; because, in different parts of the island, there are pools of stagnant water. Much vegetable decomposition takes place in the stagnant pools; and the island is in the same predicament as though it were marshy land. The soil of the Campagna of Rome, in the most fatal season, is dry; but then the Campagna is intersected with ditches and drains of water, quite sufficiently impregnated with vegetable matter to explain the aguish fevers of that country.<sup>a</sup> The fevers of Egypt begin with the subsidence of the Nile; and those of Bussorah with the subsidence of the Euphrates; and the Arabs, to revenge themselves upon the inhabitants, once<sup>b</sup> let loose the waters, and thereby produced a disease which destroyed fourteen thousand persons.<sup>c</sup> In Artois, in Flanders, the south and south-west winds come over swamps; and though the part itself is not swampy, they bring aguish complaints to it; but as soon as the wind sets in from the sea, and from the north, these aguish complaints all disappear.<sup>d</sup> These north winds, which do not come over swamps, are accompanied by very dense and durable fogs; but no ague occurs from them. The same is the case in many parts of France and the Mediterranean. In 1528, the French army, in attempting Naples, was reduced from twenty-eight thousand to four thousand men;—simply from choosing an injudicious encampment near the Baïæ.<sup>e</sup> Infinite is the mortality occasioned in this way, by ignorant or careless generals, from encamping an army near a marsh; and by governments, from permitting marshy lands to continue in the neighbourhood of cities. The instance of Walcheren must ever be a disgrace to the government of this country. “There was no reason apparent,” says Dr. Macculloch,<sup>f</sup> “for perpetuating Calcutta; when, almost from the very hour of its foundation, by Charnock, its destructive situation had been demonstrated. That Holland should have persisted in inhabiting that Batavia, which it had studied to render more poisonous than nature had already done, by the model of its own pestiferous forefather, is a problem which Holland must be allowed to explain, as it best can.”

<sup>a</sup> See Dr. Macculloch’s “Malaria;” Pages 84 and 184.

<sup>b</sup> In the year 1743. See Lind’s “Essay on Diseases incidental to Europeans in Hot Climates;” Part 1; Chapter 3; Section 4. (Second Edition; Page 110, compared with Page 128.) The following additional circumstances are there mentioned:—“The stagnating and putrefying water in the adjacent country, and the great quantity of dead and corrupted fish at that time lying upon the shore, polluted the whole atmosphere. Not above two or three of the Europeans who were settled there, escaped with life.”

<sup>c</sup> See Pages 196 and 197 of Dr. Macculloch’s “Malaria.”

<sup>d</sup> See Dr. Macculloch’s “Malaria;” Page 273.

<sup>e</sup> See Dr. Macculloch’s “Malaria;” Page 227.

<sup>f</sup> At Page 219 of his “Malaria.”

*Conditions on which Putrefaction depends.*—But although moisture is not the cause of ague, yet moisture is indispensable to the decomposition of vegetable matter; and to the disengagement of the miasma. Decomposition requires a certain degree of moisture; and if we dry any thing thoroughly, whether it be a vegetable or an animal production, we prevent decomposition. A certain degree of moisture is necessary for the fermentation and putrefaction of vegetable matter; which fermentation and putrefaction give rise to the exhalations that produce ague. Thus, it is in a moderate swamp that dry weather may put a stop to the disease;—namely, by putting a stop to putrefaction. We also see why, in extremely wet situations, there is often no ague;—because too much fluid also impedes putrefaction; but this wet, by dry weather, may be reduced to just sufficient swampiness for vegetable decomposition to take place, and malaria to be produced. Just as dryness would prevent decomposition, so will extreme wetness and moisture. If the matter which is to be decomposed, be diffused in a very large quantity of water, the putrefaction ceases, or is not evident; so that some places which, while very wet, were healthy, have been made unhealthy by being dried just sufficiently for putrefaction to go on vigorously; and, again, other parts which were dry, and which never gave out any exhalations, have been caused to do so, by a certain degree of moisture falling upon them. Thus, according to situation, the same additional moisture may produce an ill, or a salutary effect. High grounds, therefore, may suffer from the same cause which removes all unhealthiness from *low* grounds. A certain degree of rain falling upon *high* ground, will not all remain there, but will roll down. Still it has moistened the parts sufficiently for decomposition to take place above; whereas, when it comes on the *low* ground, and there collects, it may be so abundant as to dilute all the vegetable matter, and prevent it from putrefying; and may so put a stop to the unhealthiness of the part. In this way an aguish fever, whether intermittent or remittent,—for I intend to include both when I say “*aguish fever*,”—has been put a stop to by inundating a swamp; and, on the other hand, inundation has moistened a dry part sufficiently for exhalations to take place.

*Very dry or very wet Seasons check Fever.*—By recollecting this, we may explain a number of circumstances, which otherwise would appear contradictory. A river, by breaking loose over a marsh, has sometimes prevented it from being any longer the source of noxious exhalations. Where there was a marsh before, it has produced a sort of lake.<sup>a</sup> In Batavia, for example, the rainy season is comparatively healthy; because the rivers and canals are then plentifully supplied with water, which flows on rapidly; and all the marshes are inundated. But in the months of July, August, and September, the waters are nearly evaporated; and fever is then much more malignant than at any other period. On the western coast of Africa, and in some of the West India islands, especially Barbadoes, fevers are rare during the long continuance of dry weather. There is not much water there, and what there is, is evaporated in dry weather; so that the vegetable matter becomes too dry for putrefaction. Fevers, on the western coast of Africa, are observed to be arrested in long *drought*; whereas, in Batavia, they cease during the *rainy* season. At Charles Town, in South America, (which is a swampy situation,) bilious fevers prevail in hot summer weather; but in 1752 there was very intense heat, and universal health prevailed. The thermometer was 98°, even in the shade; the air was glowing; all vegetation was parched up; and decomposition was put a stop to by the intense heat. In summer, fevers frequently prevailed in certain parts, on account of the rivers diminishing to a great amount. All rivers, of course, diminish in summer; but some lose a very considerable portion of their depth; or rather, we should say, of their breadth. The lake Biviere, in Sicily, loses two-thirds of its dimensions in summer; the lake Cagliari, in Sardinia, loses much; and so does the Caspian Sea.<sup>b</sup> Of course, the sides of a river are always more or less dry; but in

<sup>a</sup> See Dr. Macculloch's "Malaria;" Page 200.

<sup>b</sup> See Dr. Macculloch's "Malaria;" Page 193.

summer a great portion becomes half-dry. There is just sufficient moisture for decomposition to take place; and therefore ague prevails when the rivers are shallow.

*The Goodwin Sands.*—A change in the course of a river, may drain a marsh completely; and in that way a part has become healthy, which before was exceedingly unhealthy. Sometimes the very reverse has taken place.\* By breaking over dry land, it has caused sufficient moisture for putrefaction to go on. The sea has done the same. It has sometimes produced the greatest unhealthiness in a neighbourhood, by making its way upon the country, and producing a permanent swamp; whereas, in other cases, it has produced something more than a swamp;—it has deposited such a body of water, that no exhalations could be given out, although before they were emitted in great abundance.<sup>a</sup> The Goodwin Sands are an instance of a cured marsh, though the land is lost.<sup>b</sup> An immense deposit of sand has filled up the marsh. The retiring of the sea will frequently cause ague; by leaving a marsh only, where the part was previously deluged.

*The Lake of Wallenstadt.*—As every river carries down a quantity of solid materials, so every river has a tendency to fill up its bed. It becomes more or less filled with solid matter, coming down from high land. A river may be completely filled up; so that the banks must be raised, or the country will become inundated. A marsh will be produced; and great unhealthiness take place. This is frequently remedied, for a time, by embanking a river; so that it shall still be confined within its proper bounds. I say “for a time” only; because the higher the river becomes,<sup>c</sup> the more slowly it runs, and the less it drains the country; till at last it is useless.<sup>d</sup> But in some countries people are prejudiced, or careless; and parts which were exceedingly healthy, become the seats of the most dreadful disease. There is an instance in Switzerland, of a part becoming very unhealthy to all around. Aguish fevers extend from the lake of Wallenstadt, over a great district, as far as Zurich. A river there (the Linth) pours its water into another river (the Mag); and that again into the lake. The Mag became stopped up, through neglect; and the neighbourhood all round, a few years ago, became one of the most pestilential districts in Switzerland;—six thousand acres being thus converted into a marsh. At last, the authorities had their attention forced to it; and it was remedied simply by turning the Linth into the lake, instead of allowing it to empty itself into the Mag; and by widening and deepening the Mag. The lake, being a deep spot, receives all that comes down from the mountains; and the whole has now a free course. The obstinacy of the people—in living in the midst of a pestilence, when they had it in their power to remedy it—is hardly to be conceived; but it is no less true. I could give many illustrations; but they all come to this point;—that a certain degree of moisture is necessary to the disengagement of malaria; that if we diminish the moisture, we diminish the malaria in one case, and increase it in another; and that if we increase the moisture, we may also produce either of these effects. Thus it is that, according to situation, circumstances the most opposite will have the same effect; and circumstances which are exactly the same, will have the most opposite effect.

*Temperature necessary for Putrefaction.*—But a certain degree of moisture, is not all that is necessary;—there must also be a certain degree of temperature. We can preserve any thing from decomposition, by an exceedingly low temperature; and by an exceedingly high temperature, we produce such changes that no decomposition can take place. We know that if meat be spoiling, we have only to cook it, and the putrefactive process is immediately arrested; and so it is with respect to the putrefaction of vegetable matter. A certain degree only of temperature is proper. If the temperature be increased, then we may have extreme decomposition,

<sup>a</sup> See Dr. Macculloch’s “Malaria;” Page 204.

<sup>b</sup> The loss of the Goodwin lands, by inundation, proved the remedy (expensive as it was) for a wide tract of poisonous marsh.—“Malaria; by John Macculloch, M. D.” Page 204.

<sup>c</sup> The Po is now, over a large tract, literally running on the summit of a wall.—“Malaria; by John Macculloch, M. D.” Page 379.

<sup>d</sup> See Dr. Macculloch’s “Malaria;” Pages 198 and 199.

and disengagement of malaria;—so that while the cold weather lasts, the people will be comparatively healthy; but when the warm weather arrives, the decomposition is such that the most fatal fevers prevail. Hence it is that aguish diseases are far more severe in hot countries, than they are in ours; and that they are far more severe in autumn, than at any other period. This, at least, is one reason; but there is another. In hot countries, and in hot seasons, there is far more vegetable matter to decompose. This is certainly to be taken into the account; but when we consider that an increase of heat produces a great increase of decomposition, we also see that fever must greatly be ascribed to the facility with which decomposition goes on in a warm temperature. A low temperature, however, may be short of that which is sufficient to stop the disengagement of malaria; and, therefore, if a country be very unhealthy, and very swampy, there will in cold weather be aguish diseases. The cold is not such as to stop putrefaction; and the land is so moist, as to produce a very considerable disengagement. The reason that ague prevails so much in the spring, is that the soil, which was caked and dried by the cold of winter, is now moistened; and the temperature of the weather has increased. The cake has consequently been broken up; and therefore we have vegetable exhalations in abundance. The vegetable matter, which was left on the ground the preceding autumn, becomes decomposed by the increased temperature. The reason that ague is so fatal in the *autumn*, is that the summer has produced a fresh stock of vegetable matter. The surface of the earth is covered by vegetable matter; it is in great part dying, and lies upon the ground to rot; the rain comes in the hot period; and—what with the heat, the moisture, and the dead vegetable matter—exhalations take place. The great abundance of the vegetable matter to be decomposed, together with the heat, renders the autumnal fevers far more severe, and far more numerous, than the vernal.

The effect of moisture has frequently been seen, in a striking way, when rain has begun suddenly after a dry season. When a quantity of vegetable matter has been lying upon the earth, and has become caked, a sudden rain has been attended, on many occasions, by the most fatal diseases. From the moistening of the vegetable matter, putrefaction has instantly taken place; and exhalations in abundance have been emitted. Again: the reason that, when the autumn is over, these fevers cease, is that the greater part of the vegetable matter has been decomposed; and the temperature of the atmosphere falls; and therefore not only is there less matter to putrefy, but the temperature is not sufficient for putrefaction to go on with vigour.

*Pasture-Lands.*—Pasture-lands, from being constantly moist, are very aguish; and yet, on breaking them up and cultivating them, they are infinitely more so;<sup>a</sup> and this from the same reasons that I have now mentioned. All pasture-lands must be unhealthy; for they are all moist;—and they cannot be good if not moist; for the grass will not grow without moisture. But when broken up, they become more unhealthy. Previously, only *portions* died; but, when the lands are broken up, nearly all the vegetable matter is killed, and rushes into putrefaction;—so that it is always found, that the breaking up of pasture-lands is attended by far more disease, than existed before the land was so broken up. It may be a fact, however, that malaria is let loose from the earth by breaking it up. It is said that, in many countries, on the breaking up of the surface of the earth, these fevers are sure to prevail. In the West Indies, for instance, it is said that this process has been known, for two centuries, to be exceedingly dangerous. Cassan mentions that fevers, like the plague, will take place on land being broken up;—so that labourers will sometimes die on the spot, if they remain there all night; whereas no harm arises if they be not broken up. Volney, the traveller, mentions this as an invariable observation in America.<sup>b</sup>

*Clearing of Woods.*—It is found also,—and the fact is precisely similar,—that on clearing away woods, the disease especially prevails. A quantity of malaria is

<sup>a</sup> See Dr. Macculloch's "Malaria;" Pages 111 and 112.

<sup>b</sup> See Dr. Macculloch's "Malaria;" Page 113.

let loose from the forest, when the woods are cleared; and—more than that—a quantity of vegetable matter necessarily lies on the surface of the earth, which, although kept moist enough for decomposition, is prevented from decaying much, from the inability of the sun to penetrate to it; but, on clearing the wood, the heat of the sun is admitted to the surface, where the vegetable matter is lying; and it then falls into a state of rapid decomposition.<sup>a</sup> Hence it is found that the clearing of woods is always a dangerous process; and it may be so from two circumstances;—first, the malaria which is pent up in the woods is let loose; and secondly, the sun has access to the vegetable matter which lies on the surface, and effects its decomposition. Besides, much vegetable matter must be killed by the process. It is said that the same effect will take place in Italy, if certain bushes be cut down.<sup>b</sup> Whatever malaria may be in them, has then an opportunity to escape; and fever is sure to prevail. The removal of woods has frequently been injurious, in another point of view;—by removing a protection. Some villages have been free from ague, while a wood existed between them and a marsh; but on cutting down the wood, they have become from that moment exceedingly unhealthy;—the wood having served the purpose of a screen.<sup>c</sup> Some have imagined that it was the knowledge of this circumstance,—of this advantage of woods,—that caused them to be so venerated, and held so sacred in ancient times.

*Stagnant Water.*—It has been said that stagnant water alone will produce ague, without any vegetable matter being in it; but we are to remember that this stagnant water will putrefy; which it certainly would not, unless it contained animal or vegetable matter. Water itself—pure oxygen and hydrogen—cannot undergo putrefaction; but soft water will putrefy; and, as that is the case, it must contain dead vegetable matter. If stagnant water, therefore,—although nothing can be seen in it,—does produce ague, we may explain the occurrence by supposing that it contains vegetable matter. It is well known that the Thames water, however good it may look, when put into casks will putrefy; and it is said that the decay of the interior surface of the cask, is quite sufficient to explain this;—that if pure water be put into a cask, yet the wood of the cask—being vegetable matter, and being next the water—becomes more or less acted upon by the water, and more or less undergoes the process of putrefaction, and so affords malaria.<sup>d</sup> It is on account of this liability of the wood to be destroyed, that casks are always charred within; by which they are enabled to resist the putrefactive process.

Any portion of water (however small the collection) containing decayed vegetable matter, is sufficient to cause intermittent fever. Many places, therefore, which have only a small pond, or a small lake, produce disease. Many places, no doubt, are suffered to give ague, and aguish diseases, from circumstances which are entirely within control. It is said that an inveterate ague was produced by the canal at Versailles, though it was little larger than a fish-pond.<sup>e</sup> Monfalcon quotes an instance of a fish-pond at Chantilly, which was remarkable for its pestiferous character.<sup>f</sup> Many country residences (there can be no question) have been made unhealthy, from the custom of ornamenting them with woods, and little lakes of stagnant water;—“*pièces d'eau d'agrément*,” as the French call them;—“*lacs artificiels*.”<sup>g</sup> Edinburgh is now any thing but favourable to ague; but there was formerly in it a lake, called “the North Loch,” which was famous for it.<sup>h</sup> Agues prevailed in that district till the spot was drained; but now no agues are there at all. When I say “ague,” I mean fevers of an aguish character,—whether remittent or intermittent; and many diseases of this description are unquestionably

<sup>a</sup> See Dr. Macculloch's “Malaria,” Page 44.

<sup>b</sup> See Dr. Macculloch's “Malaria,” Pages 267 and 268.

<sup>c</sup> See Dr. Macculloch's “Malaria,” Pages 43, 44, 248 and 249.

<sup>d</sup> See Dr. Macculloch's “Malaria,” Page 143.

<sup>e</sup> See Dr. Macculloch's “Malaria,” Page 100.

<sup>f</sup> He [Monfalcon] refers pointedly to the artificial water of Chantilly, as the source of frequent and serious epidemics.—“*Malaria; by John Macculloch, M. D.*” Page 100.

<sup>g</sup> See Monfalcon's opinion, recorded at Page 99 of Dr. Macculloch's “Malaria.”

<sup>h</sup> See Dr. Macculloch's “Malaria,” Page 191.

mistaken, every day, for real typhus. In order to the existence of ague, the situation need not be low, nor need there be a marsh. At whatever height water be hemmed in, of course vegetable decay may take place;—just as though it were in a low situation.

*Clayey and Retentive Soils.*—Clayey soils are the most favourable for these fevers, on account of the clay retaining the moisture; whereas gravelly soils let it escape.<sup>a</sup> It might be imagined, perhaps, that the Delta of the Nile would be a great source of ague. Ague (Sir James McGrigor says) is not unknown in Lower Egypt; but it is only seen sporadically. The reason of this is, that there is no stagnation of water;—notwithstanding the existence of so much vegetable matter as is brought down to the Delta. In fact, there is so much agitation, as to have the same effect as too much water; so that putrefaction does not take place. Strabo remarks the healthiness of Lower Egypt; and ascribes it to this cause. On the other hand, ague will continually occur in spots where there is little more than a pool, or a puddle; but then the water is completely stationary. Even a ship may contain a source of malaria. I believe the fevers of ships, are very often *remittent* fevers; but are mistaken for *typhus*. They have often arisen entirely from the bilge water. Captain Smith says, he never knew fever in any of his ships, during a long service in the Mediterranean; and Captains Parry, Cook, and Sir Henry Baynton, all succeeded in preserving the health of their crews. They all had the holds of their vessels washed out daily, by means of plugs, till the water came out perfectly clear; so that no accumulation of filth could take place;—no accumulation of vegetable matter. This fact may be contrasted with one relative to the *Powerful*, a seventy-four gun ship; the crew of which, on their voyage from the East Indies, were nearly all disabled by fever; and the cause was found to be merely the ballast, which consisted of moist and putrid mud. Ships laden with sugar have the greatest mortality; and sugar is a vegetable matter. In fact, the most unhealthy cargo that a ship can carry, is sugar.<sup>b</sup>

*Moats and Ditches.*—The castle of Flamandville, in Normandy, is situated high; but an endemic prevails around, in consequence of a mere moat, containing a quantity of vegetable matter, which gives forth pestiferous effluvia. A family, resident at the place for a length of time, was at last exterminated; but, before that, they underwent a loss both of mental and of corporeal power. The same thing has been observed in the neighbourhood of many castles. The besieged and the besieging have both suffered, when the baronial castles were attacked; and the source of all the disease, was the moat surrounding the castle. The sentries were the first attacked.<sup>c</sup> Down to the middle of the last century, one-third of the inhabitants at Bourg en Bresse were incapacitated; in consequence of the ditches, around the fortifications, containing a quantity of decayed vegetable matter. At Havre de Grace the soldiers were once known to be giddy, and to experience violent headache, five minutes after they had approached the ditches; and then they had violent fever.<sup>d</sup> I saw several cases of ague in London, arising from the moat around the Tower. A stupid negligence, with regard to the moat, prevailed for a long time; a great accumulation of filth took place; and I continually saw patients with ague, from that part of London. The first case I met with, was that of a lady;—a relative of a medical gentleman in the neighbourhood; and, not having been in the country, she could not imagine how she had contracted the ague. At last she told me, that she was in the habit of taking exercise on the ramparts of the Tower; and the circumstance of the moat, of which I had read so much in books, immediately occurred to my mind. I inquired whether it was in a filthy condition; and learned that it was so; but that the authorities would not clean it out. There was a difference of opinion as to which department it belonged to; and some medical men (laughingly) said, that it could not be supposed they should press the subject;

<sup>a</sup> See Dr. Macculloch's "Malaria;" Page 20.

<sup>b</sup> See Dr. Macculloch's "Malaria;" Pages 146 to 148.

<sup>d</sup> See Dr. Macculloch's "Malaria;" Page 93.

because it brought "grist to the mill." I believe, however, that (in consequence of the representations of the profession) it has been cleansed.

Harbours, moats, and mill-dams, have all been sources of ague. In a mill-dam the stream is rapid; but the sides may be flat and wet.<sup>a</sup> Flax-grounds have frequently been proved to have given origin to the same disease; in consequence of the flax lying upon the ground, in a state of decay. In Italy and Germany, fevers frequently prevail in the neighbourhood of flax-grounds; and there are instances of ague in dry, sandy, high places, owing to the hemp being dried there; and the fevers regularly cease when the season for drying hemp is over. Indigo-manufactories have also been the sources of this disease.<sup>b</sup> The inundation of a cellar, has frequently caused these fevers to prevail in a family; and the passage of a drain under a house, has frequently caused the inhabitants to continue the victims of fever;—that is to say, the house has been rendered unhealthy; and all the people residing in it, have been more or less attacked with fever, from time to time. Nay, the removal of stores has frequently been productive of fever.<sup>c</sup> The water, under the stores, has been impregnated with vegetable matter, in a state of putrefaction. The removal of the stores has let loose the exhalations, which were pent up beneath them; and the men employed in removing them, have been known to suffer an attack of fever.

*High Susceptibility of some Persons.*—When we consider the peculiar susceptibilities of different individuals to the effects of morbid causes, we shall not be surprised that persons will occasionally catch an ague, from the most trivial exposure to malaria. We know that some persons are singularly liable to be affected by particular causes. Many persons, on approaching a hay-field, will be seized with asthma; particularly if the grass be sweet-scented. I believe it is not the hay which produces the affection, but the flower of the grass;—so that they are attacked if they approach fields at the time they are in flower; which is at the period of hay-making. It is said to be not at all uncommon, for persons to be so affected from ipecacuanha. Some persons have been seized with asthma, from ipecacuanha being powdered in the house; nay, it is said that some persons have been seized with it, merely from a box of ipecacuanha-lozenges being in the same room. At any rate, a trivial exposure to this drug, frequently produces the disease. We must have seen persons thrown into a violent salivation, from a grain of calomel; nay, I have seen it arise from the application of a little red precipitate ointment,<sup>d</sup> or mercurial ointment, to a sore leg. From these various circumstances, we must suppose that there are some people, who are peculiarly susceptible of the effects of malaria; and therefore I can imagine sporadic cases of ague to take place, from a person merely passing through a market, in which decayed cabbage-leaves may be lying. We all know that there is more or less putridity in these vegetable remains;—they continually emit a noxious smell; and I can conceive that, even in a most healthy town, we may thus have a cause of ague. Ague is sometimes ascribable to very common and trifling causes, without at all invalidating our general conclusions. A very slight collection of decayed vegetable matter may be supposed sufficient to produce ague, in a person extraordinarily disposed to it; and therefore, when we cannot account for the existence of the affection from the person having been near a swamp, it is very possible that the case may be one of extreme susceptibility;—that a minute quantity of putrid vegetable matter, has been near the patient; or that minute malarious exhalations have been wafted to him. It is to be remembered, that these miasmata will extend to a very great distance; and that, in very aguish seasons, places which are usually healthy, and not situated near much stagnant water, frequently become unhealthy. Dr. Macculloch's works are the

<sup>d</sup> Unguentum Hydrargyri Nitrico-Oxydi.

best on this subject. They consist of two volumes on Marsh-Fever and Neuralgia;<sup>a</sup> and one volume on Malaria.<sup>b</sup> It is his opinion,—and also that of several Italian physicians, and able military men,—that a single inspiration of malaria, may be quite sufficient to cause disease.<sup>c</sup> If all this be the case (and there is no reason to doubt it), we are not by any means to reject the belief that the disease always rises from such exhalations, merely because we can hardly tell how a particular individual, in certain circumstances, may have been exposed to them.

*Distance to which Malaria may extend from its Source.*—As to the distance to which malaria will extend, it is said that, in Italy, the ill effects of stagnant water are known to extend three miles;—that they have reached from the lake Agnano, as far as the convent of Camaldoli, which is situated on a high hill.<sup>d</sup> Lancisi (who first referred this disease to marsh-miasmata) says, that as thirty ladies and gentlemen were making an excursion of pleasure up the Tiber, the wind suddenly shifted to the south,—coming over the Pontine marshes; and twenty-nine were instantly taken ill;—only one escaping. They were all well before; but the wind coming over the Pontine marshes was impregnated with malaria; and twenty-nine were instantly affected by it. Dr. Lind, of Haslar Hospital, (who wrote on the Diseases of Hot Climates,) says that when Commodore Long's squadron lay off the mouth of the Tiber, two vessels that were close to the shore were affected, while the rest, lying a little farther off, escaped. The difference of half a cable's length from the shore, has caused vessels to suffer or escape; yet Sir Gilbert Blane says that, in the West Indies, (and he heard the same respecting the channel leading to Calcutta,) the malaria was observed to reach a distance of three thousand feet, and more. In Zealand, the distance (he believes) is far less;—owing to the comparative mildness of the malaria, and also of the temperature. It is the opinion of many authors, that the hotter the climate, the farther does the malaria extend;—that if the quantity of vegetable matter be great, and the heat intense, it produces its effects at a very considerable distance; but that in cold climates, the vegetable matter and heat being less, the exhalations are milder in their nature, and less copious; and therefore it is supposed by Sir Gilbert Blane (who had great experience), that in Zealand the distance is far less, than in many other parts. He says that, at the time of the Walcheren fever, no persons on board ship were seized with the disease which was prevailing on shore; although the channel between Beveland and Flushing was only six thousand feet wide, and some of the ships lay nearer to one shore than the half of that distance. It is the opinion of many, that the malaria will not extend to any great distance. Sir Gilbert mentions, that when the ships watered at Rockford, he found that if they anchored so near the shore as to smell the land,—the smell of land-air being sometimes very perceptible at sea,—they were affected; but if they remained only two cables' length from the spot where they smelt the malaria, no inconvenience was experienced. It is said by Lind that, at Pensacola,<sup>e</sup> a regiment lost a hundred and twenty men, and eleven out of twelve officers' wives who landed; but the whole crew of a man-of-war, which was lying one mile from the shore, remained perfectly healthy.<sup>f</sup> However, Dr. Macculloch believes that malaria may be conveyed to an indefinite distance.<sup>g</sup> He has investigated this subject more than any one else; but has carried

<sup>a</sup> "Essay on the Remittent and Intermittent Diseases; including Marsh-Fever and Neuralgia; by John Macculloch, M.D."

<sup>b</sup> "Malaria: an Essay on the Production and Propagation of this Poison. By John Macculloch, M.D."

<sup>c</sup> It is matter of observation, that a minute's exposure to Malaria,—a single inspiration, probably, is sufficient to excite its fever; and, very notoriously, to re-excite it in those who are subject to that morbid sensibility, derived from former or habitual fevers.—"Malaria; by John Macculloch, M.D." Pages 53 and 54.

<sup>d</sup> See Dr. Macculloch's "Malaria;" Pages 241 and 242.

<sup>e</sup> In North America.

<sup>f</sup> This occurred in the year 1765. See Lind's "Essay on Diseases incidental to Europeans in Hot Climates;" Part 2; Chapter 1; Section 2. (Second Edition; Page 169.)

<sup>g</sup> See his remarks on the "Propagation of Malaria" (forming Chapter 7 of his Work); particularly Pages 308 to 336.

his views further, perhaps, than most other persons will think justifiable. He is convinced<sup>a</sup> that it is conveyed from the banks of the Thames, over the hills of Kent; even to a distance of some miles from the coast.<sup>b</sup> He argues<sup>c</sup> in the first place, analogically, that dogs will smell the land long before it is visible; and, on the other hand, that the sea may be smelt<sup>d</sup> very far inland;—that whales or sharks may be smelt, both powerfully and offensively, as far as the spouting of the animal is visible from the mast-head; and therefore he says,<sup>e</sup> that if these things can reach such a distance, and odours produce such an effect, so may malaria or vegetable exhalations. He mentions,<sup>f</sup> that fogs and clouds go to an immense distance;—that malaria easily unites with fogs and clouds; and therefore he concludes, that as far as these will go, so far may the malaria extend. Moreover he asserts,<sup>g</sup> as a fact, that he has found records in ships' books, of malaria having produced fever at a distance of five or six miles or more from shore; and that the danger was instantly made sensible by the smell;—so that the ship's crew would go below, or weigh anchor and run to sea. He says<sup>h</sup> it is well known, that points in the coasts of Suffolk and Norfolk, and the eastern coast of Scotland, have ague; though there is no local source of malaria for many miles; and that there are some points where there is no source of malaria, for even a greater distance than that; and therefore he contends<sup>i</sup> that it must be brought from Holland, and the northern shores of the Continent.

*Influence of Easterly Winds.*—The effect of the east wind, in causing and renewing aguish diseases, is well known; but it can no more be the simple air itself, than pure water (oxygen and hydrogen) can produce ague. Wind, if pure, can no more be poisonous than pure water;<sup>k</sup> and therefore the noxious property must be, as in the case of water, *contained* in it. Now the east wind is perfectly innocuous, in the regions which it reaches after having passed over healthy countries; and, *vice versa*, other winds are as unhealthy in some parts of the world, as the east wind is here;—that is, where those winds come over a marshy district; exactly as our east winds do. This is another argument adopted by Dr. Macculloch.<sup>l</sup> He says<sup>m</sup>,—still pursuing his argument,—that land under the trade-winds, and ships in the equatorial seas, escape; and that St. Helena, being so much exposed to the east wind, ought never to be free from ague; whereas that is not the case. If the east wind blows over a frozen continent, or simply blows across the sea, (though of course, in its passage, it must imbibe moisture,) it is found to do no harm. In order to be injurious, it must blow over land where there is vegetable matter and moisture. For this reason, in one-half of the globe, the east wind is exceedingly injurious from the month of March to the month of October." In French Flanders,

<sup>a</sup> He states that conviction at Page 309 of his "Malaria."

<sup>b</sup> From any known and often very limited spot, this poison will proceed (through the air, or on the winds) to distances of three or four miles;—exciting as much virulence as in its native marsh. This—to quote a familiar domestic example, out of hundreds that might be adduced—occurs on the hills of Kent, far from the marshes of Erith, Northfleet, or Gravesend.—"Malaria; by John Macculloch, M. D." Page 54.

<sup>c</sup> At Page 310 of his "Malaria."

<sup>d</sup> The smell of the sea is, in reality, the smell from fish.—"Malaria; by John Macculloch, M. D." Page 310.

<sup>e</sup> At Pages 309 and 310 of his "Malaria."

<sup>f</sup> At Pages 310 and 311 of his "Malaria."

<sup>g</sup> At Page 314 of his "Malaria." In addition to this general assertion, he gives the following specific instance; in which, however, the distance is rather less, than in the case referred to in the text:—"In one case of a healthy ship and crew, anchored at least four miles from the shore, a sudden change of wind brought out the smell of the land; on which orders were immediately given for weighing the anchor; while, even before the cable-chain could be cleared, most of the men working at it (who were the only ones first permitted on deck), were seized with a disease, which proved the fatal cholera to the greatest number."—"Malaria;" Pages 314 and 315.)

<sup>h</sup> At Page 317 of his "Malaria."

<sup>i</sup> At Pages 317 and 318 of his "Malaria."

<sup>k</sup> See Page 318 of Dr. Macculloch's "Malaria."

<sup>l</sup> For this argument, see Pages 316 to 336 of his "Malaria."

<sup>m</sup> At Page 319 of his "Malaria."

<sup>n</sup> See Page 320 of Dr. Macculloch's "Malaria."

the south and south-west winds do the same harm, as the east wind in other countries.<sup>a</sup> The east wind in summer is dry.<sup>b</sup> Hence it has less conducting power; and thus, though we get ague from the Dutch ditches in *spring*,<sup>c</sup> we do not get their remittent fevers of *autumn*. The east wind is so dry at that time, that it will not conduct the malaria; for a certain degree of moisture is as necessary for its conveyance, as for its production.

To show the healthiness of the east wind, where it does not pass over a marshy district, I may mention that it is the salutary breeze of the burning islands of Western America; while many parts of France, Germany, Poland, and Russia, never feel its injurious effects.<sup>d</sup> Dr. Macculloch says,<sup>e</sup> that although "the east wind, after sweeping the burning sands of Africa, makes the side of Sardinia which is exposed to it a desert, and in Minorca will not suffer an orange-leaf to protrude beyond a garden-wall, it is before the east wind that Mount Edgumbe roots its splendid trees even into the sea;—not daring to show a leaf to the western ones; while in Southampton river it is precisely the reverse."

*The Harmattan.*—The east wind, from its excessive heat and dryness, or from its coldness and moisture, may be injurious in other ways than in producing intermittent fever. The Harmattan<sup>f</sup> will not produce ague; but it is excessively hot and dry,<sup>g</sup> and therefore an injurious wind. Again: all experience an unpleasant feeling from the east wind in spring;—not by its producing ague, but by its being excessively cold, and excessively moist.

*Elevated Situations exposed to the Influence of Malaria.*—Distant parts suffer more if they be hilly than if flat; and frequently the immediate neighbourhood of a marsh will escape in some measure, while a village or a town at some distance, if it be situated on a hill, suffers exceedingly. This fact seems to be capable of explanation, from the circumstance of hills attracting from the clouds their moisture, and every thing united with it. Malaria is conducted by moisture, and moves with the clouds; and the clouds, being attracted to the sides of a hill, deposit their moisture and every thing else they contain; and thus a hilly part may suffer much, although it is situated at a great distance from a marsh. I mentioned<sup>h</sup> that the inmates of the convent of Camaldoli, which is situated three miles from the lake Agnano, suffer from ague. It stands upon a high hill. At Malta, the malaria produced under a cliff, never affects the spot itself; but produces direful consequences on a village situated above it.<sup>i</sup> At Weymouth (in our own country), it is said that "the back-water" rarely affects the immediate inhabitants; while those at a distance suffer. At St. Austle, in Cornwall, the disease prevails from some marshes at St. Blaisey. At Erith there is less ague in general, than could be expected; but houses that are situated high above it, often suffer very severely.

*Influence of Currents.*—Sometimes a distant part will suffer, not from clouds conveying the moisture, but from currents of air. The locality of a part may be such, that a current will proceed in some particular direction. If currents pass over a swamp, the part exposed to them will necessarily suffer; and if there be a pecu-

<sup>f</sup> A prevailing wind on the coast of Africa, between Cape Verd and Cape Lopez, in the months of December, January, and February. It is a particularly dry wind,—from passing over the burning deserts of Africa; so much so, that, in a very short time, the leaves of plants become dry and crisp, and the skin of human beings dry and chapped, the nose and lips sore, the fauces arid, and the perspiration acrid; yet it is not pestilential; but, on the contrary, puts an end to epidemic diseases.—Dr. Hooper's "Medical Dictionary;" Seventh Edition; Article "Harmattan."

<sup>g</sup> See Dr. Macculloch's "Malaria;" Pages 320 and 331.

<sup>h</sup> See Page 253.

<sup>i</sup> According to Dr. Macculloch, the malaria sometimes leads to the abandonment of this village. For this circumstance, and for the facts stated in the text respecting Weymouth, Erith, St. Austle, and St. Blaisey, see Pages 242 and 243 of his "Malaria."

liarity in a current, it will affect a part which, *à priori*, would not be expected to suffer. Captain Smith, in his "Statistical Table of Sicily," mentions seventy-six unhealthy towns and villages; and, out of that number, thirty-five are situated on hills or declivities, and at a great distance from a marsh. When the wind blows from the south, being a warm wind, it has a tendency to ascend; and it is supposed that the southern wind—blowing over a marsh, and tending upwards by its temperature—affects high towns; while the colder northern wind does not affect those houses situated on the other side of the swamps, though placed equally high.<sup>a</sup> We can easily conceive of a swamp, and towns on each side. When the wind blows *south* it will ascend, and high houses will suffer; whereas, if it blow *north*, it will not ascend to a house of the same elevation, but will remain near the earth; and in that way the house will suffer very little; or not at all. Hence we must take into account a number of circumstances, when ague prevails in districts, where there is no marsh in the immediate neighbourhood.

*Partial Influence of Malaria in some Districts.*—In the prevalence of this disease, however, there are singularities, which cannot be explained;—at least many, perhaps, will not be satisfied with the explanation that is given. It is said, that on the high road to Chatham and Feversham,—comprising a distance of twenty miles,—the effect of malaria is only noticed on one side of the road.<sup>b</sup> The injurious lands which afford the malaria, are situated about a mile off; but it is only detached houses on one side of a level road, that suffer. It is to be remembered, however, that the dews will spread in a similar way;—that they will spread to a particular spot, or stop at a certain bush. Every one may notice the same circumstance, in the case of a hoar-frost. Now, as far as these will extend, so may malaria; and they will explain the singularity of such an occurrence, in some instances. Dr. Bancroft was credibly informed, that only one side of a particular street in Rome, was affected by ague or aguish diseases; and Baglivi says, that the healthy spots of Rome are separated from the unhealthy by a wonderfully short distance. A similar circumstance is observed in Cadiz; and in many American states. In the latter, however, the reason is perfectly evident;—some streets are exceedingly low; and are built in districts near which there is a quantity of stagnant water.

*Lower Strata of Air generally Most Dangerous.*—It is in consequence either of the weight of these pestiferous exhalations, or of their uniting with moisture, and producing their effect when the moisture is deposited, that the lowest spots are generally the most dangerous; and this also accounts for these exhalations being most dangerous at night; for it may be laid down as a general rule, that malaria is most dangerous in a low situation and in the night. It is on the ground, and near the lowest parts of a house, that moisture is deposited; and, that being the case, the exhalations of malaria will be let loose there; and what is lowest will suffer most. Again: in the night the cold is greater than in the day; and, from the cold being greater, moisture is deposited, and with the moisture malaria. Hence we have, in general, a sufficient explanation for the two facts I have just stated.

I could give you plenty of instances of the influence of difference in elevation, in causing a liability to ague. In the barracks of Spanish Town, Jamaica, there were three cases of fever in the *lower* story, for one in the *upper*.<sup>c</sup> Sir Gilbert Blane says he was informed, by a medical man, that in 1781, at St. Lucia, one regiment, situated on the *top* of a hill, lost two hundred and seventy-one men, from intermittent and remittent fever; another regiment, on the *sides* of the hill, lost three hundred and eighteen; and a third, which stayed at the *bottom* of the hill, lost four hundred and eighty-six. The hill was called "Morne Fortuné;" and was situated eight hundred and seventy-two feet above the level of the sea. At Walcheren, the natives knew that those who slept in the upper stories, were far less liable to disease than those in the lower; and that if they caught ague, it was much milder. Sir

<sup>a</sup> See Dr. Macculloch's "Malaria;" Page 244.

<sup>b</sup> The ague is unknown on the right side.—"Malaria; by John Macculloch, M.D." Page 261.

<sup>c</sup> See Dr. Macculloch's "Malaria;" Page 265.

Gilbert Blane also says he was informed, by Dr. Ferguson, that at St. Domingo two-thirds more were taken ill on the *ground* floor than on the *upper* floor. In Italy the difference is so great, that an *erect* is known to be more safe, than a *sitting* or a *lying* posture. Although this is a general rule, however, yet there are exceptions to it. In some parts of Norfolk, danger is confined to the *upper* stories;<sup>a</sup> but in those places there must be a particular current, which wafts the malaria in that direction.

*Malaria most potent at Night.*—The great danger of night is always strikingly illustrated. Dr. Lind says<sup>b</sup> that, in 1766, when the ship *Phoenix* lay at anchor for twenty-seven days at St. Thomas's, two hundred and eighty men, constituting nearly all the ship's company, went on shore, in parties of twenty or thirty, and rambled about the island; but none of those who did not remain on shore at night suffered; while none of those who slept on shore escaped sickness, and only three survived. Dr. Lind mentions<sup>c</sup> that, at Batavia, a boat belonging to "the Medway," was actually manned three times;—every one having perished; and simply from the men having to attend duty on shore, every night. It is found, that a cold night after a hot day is much the worst. During the heat of the day, there is more disengagement of malaria; and consequently, when night comes on, there is far more to be precipitated. Cold and wet are always most operative after heat. It is thought by some, that in Italy evening is more dangerous than night; and that there is no hazard after nine or ten at night. If this be a fact, I presume it arises from the whole quantity of malaria being by that time deposited.<sup>d</sup> The effect of night, however, must be ascribed in some measure to mere sleep. It is right to take every thing into consideration; and all morbid causes act more powerfully in sleep, than in the waking state.<sup>e</sup> Sleeping on damp ground at night is injurious; not merely because the person has lain upon the ground, nor simply because he has lain there during the night; but because he has lain on the lowest spot, at a time when there is more malaria than in the daytime, and when the body is less capable of resisting it than in the day.

*Malaria Precipitated with Rain.*—Lind<sup>f</sup> and Mungo Park<sup>g</sup> were convinced, that malaria was precipitated with the rain; and in this way they noticed, frequently, that rain was unhealthy. Park says that, on one occasion, the rain had not begun more than three minutes, before many soldiers seemed drunk, and fell asleep; while others vomited; and he mentions that, in a storm, he himself felt disposed to sleep; and could not help it, although he was on damp, and therefore dangerous ground. Dr. Lind says,<sup>h</sup> that the most unhealthy rains in Guinea, are those which occur first in the wet season; (which looks as if malaria were precipitated in the rain;) that in forty-eight hours, the rain rotted their shoes; and

<sup>b</sup> In his "Essay on Diseases incidental to Europeans in Hot Climates;" Part 2; Chapter 2; Section 5. (Second Edition; Pages 235 to 239.)

<sup>c</sup> In his "Essay on Diseases incidental to Europeans in Hot Climates;" Part 1; Chapter 4; Section 3. (Second Edition; Page 148.) The circumstance occurred in the year 1764; as will be seen by referring to the Essay just mentioned; Part 1; Chapter 3; Section 3. (Second Edition; Page 98.)

<sup>d</sup> See Dr. Macculloch's "Malaria;" Pages 277 and 278.

<sup>e</sup> See Dr. Macculloch's "Malaria;" Pages 280 and 281.

<sup>f</sup> Lind says that, even in England, a rainy season will produce remittents and intermittents, in the healthiest districts, or where malaria is unknown.—"Malaria; by John Macculloch, M.D.;" Page 277.

<sup>g</sup> Respecting the production of remittent fever, there is an assertion in which there may (or rather *must*) be a fallacy involved. According to the testimony of African travellers, and of Park in particular, it is produced immediately on the fall of rains;—as if the mere contact of the rain itself was the cause.—"Malaria; by John Macculloch, M.D." Page 158.

<sup>h</sup> In his "Essay on the Diseases incidental to Europeans in Hot Climates;" Part 1; Chapter 2; Section 2. (Second Edition; Page 47 and 48.) The following additional particulars are there recorded:—"They (the first rains) stain clothes more than other rains; and, soon after their commencement, the ground, even in places formerly dry and parched, swarms with frogs. At this time, skins quickly generate large worms; and it is remarked that the fowls, which greedily prey on other insects, refuse to feed on these."

that when the clothes they had on were hung up to dry in the sun, they became, in a few hours, full of maggots;—showing, probably, that much injurious matter was contained in the moisture, and deposited with the rain. As the rain falls more and more, there is generally less and less unhealthiness. This may be ascribed to two circumstances;—in the first place, to the quantity of malaria deposited by the first rain; and, secondly, to the continued rain which falls upon the earth;—producing so much moisture, that vegetable decomposition will not so easily go on. Hence, again, disease increases when the moisture declines.

The power of moisture to dissolve these exhalations, is rendered exceedingly probable from the fact, that a stench arises from pools and privies in damp weather. Every thing that affords an offensive smell, becomes worse in wet weather; and therefore the exhalations that produce ague, will also probably rise far more in wet weather than in dry. The effect of moisture is sufficiently seen in the increase of illness.

*Does Sea-Water prevent Malaria?*—It has been well thought, by some, that a mixture of salt water with fresh prevents this injurious decomposition.<sup>a</sup> However, this is a mistake; for salt marshes, which are principally situated in the south, will give rise to ague in summer. For instance: around the Dol, in Normandy, where there is a salt marsh, scarcely an inhabitant escapes ague.<sup>b</sup> Very often there is a severe intermittent fever in Holland, after an inundation of the sea; and even when a place is well washed,—as Heron Bay, for instance, and the district around Reculver,<sup>c</sup>—agueish fevers frequently prevail.<sup>d</sup> On the other hand, it has been contended,<sup>e</sup> that a certain portion of sea-water *augments* the prevalence of this miasma. This would be not at all to be wondered at; because it is a mere hypothesis that salt water prevents it. Sea-weed, being vegetable matter, has actually been the source of fevers of this description:

*Influence of Different Plants and Soils in the Production of Malaria.*—It is very probable that certain plants, and certain soils, are more favourable to the production of malaria than others; for sometimes there is malaria in spots where we should not suspect it;—where the grass looks fresh and green; and where no signs of decomposition are observed; whereas, in other parts, where there is a degree of decomposition, persons are perfectly safe. A friend of mine, who was travelling in Syria, saw a spot of grass fresh and green, though rather moist; and he intended to pitch his tent there for the night. But he was warned by some of the people of the country; who rode in haste to him; and implored him, as he valued his life and the lives of his retinue, not to pitch his tent there. He could not conceive why; and they told him that whoever remained on that spot at night, was sure to be seized with severe fever. There was nothing in the appearance of the grass, that could lead him to suspect any thing of the kind; but, of course, the lower portions were constantly dying and decomposing. It is, as I have just said, the opinion of many, that certain soils, and certain varieties of vegetable matter, are peculiarly favourable to the production of this malaria. Such would appear to be the fact, and very possibly is so; but whether this is to be attributed to the nature of the soil, or to the existence of certain plants, rather than of others, I do not know. Some believe, that the different kinds of ague arise from a difference in the vegetable matter. It is said, for instance, that tertians particularly prevail in Germany; that in Italy quotidians are most frequently seen; that in Hungary fevers of this description are particularly attended with petechiæ; and the exhalations of the Pontine marshes, are said to produce fevers with short intermissions. Holland is remarkable for producing all sorts of fever;—quotidians, tertians, quartans, and every other variety. In Spain, Africa, and America, these fevers are remarkable for being

<sup>a</sup> It is a common popular conviction, that salt marshes are innocent.—“*Malaria; by John Macculloch, M.D.*,” Page 35.

<sup>b</sup> See Page 36 of Dr. Macculloch’s “*Malaria*.”

<sup>c</sup> Near Margate.

<sup>d</sup> See Page 39 of Dr. Macculloch’s “*Malaria*.”

<sup>e</sup> By many French and Italian writers, alluded to by Dr. Macculloch, at Page 37 of his “*Malaria*.”

attended with black vomit, and with yellowness of the skin. In some parts of Italy, these fevers are particularly attended by apoplexy; and in many parts they are particularly followed, or accompanied, by neuralgia. In India and Africa, the *liver* chiefly suffers; at Walcheren the *spleen*. Even parts not distant from each other, are sometimes thus distinguished.<sup>a</sup> It thus appears that there are many peculiarities, according to situation; but whether this is to be explained by a variety in the malaria, I do not know.

*Peat-Bog.*—There is one description of bog, which does not produce malaria;—namely, peat-bog. But here there is no putrefaction;—decomposition having taken place in a peculiar manner. The vegetable matter becomes carbonized; and there is not sufficient heat for putrefaction to occur. But it is said that peat-moss, when in a certain latitude and on a certain level, can putrefy; and then, I believe, ague does prevail. That peat-bog does not putrefy, is shown by a fact stated on good authority; namely, that animal matter thrown into it will not putrefy; but it is said that where peat-moss is placed in situations where it is warmer, and upon a proper level for moisture, it will putrefy and produce ague;—just as other kinds of vegetable matter will do.<sup>b</sup>

*Animal Matter does not produce Malaria.*—Now that it is *vegetable*, and not *animal* matter, which produces ague, is proved by this circumstance;—that no person has this disease from being exposed to the most intense animal exhalations. Thousands of carcasses are annually employed in many manufactories; as, for example, in manufactories of sal ammoniac; and yet no person is known to contract an ague from them. Indeed, so far from it, that the most crowded places generally escape intermittent fevers. That part of Rome inhabited by the Jews, and called “the *Judaicum*,” is full of animal filth; but it escapes ague; while the elegant streets in the neighbourhood, suffer from it very severely.<sup>c</sup>

*Influence of Fire and Smoke in preventing Ague.*—Fire and smoke (especially tobacco-smoke) appear to keep away ague.<sup>d</sup> Malaria not being the produce of dead *animal* matter, or effluvia arising from living bodies, but of *vegetable* exhalations, the more men and animals are crowded together, the less access is there for the malaria; and it is generally supposed that the addition of smoke, of every description, has a great tendency to prevent it; and therefore those who live in the most smoky, crowded, dirty places, are situated in the most favourable manner with respect to ague. It was once imagined, however, that the smoke of coal was particularly injurious; and therefore it was made a capital offence to burn coal in London; and forges were only allowed in the vicinity. Sir Gilbert Blane mentions that, in the Tower, there is a document relating to a person who was executed in the time of Edward the First, for burning coal in London;<sup>e</sup> though it has since been considered to be a great promoter of health. Perhaps smoke—whether of coal, of wood, or of tobacco—may act by merely taking the place of the exhalations, and preventing them more or less from entering. It may be, however, that they act by their warmth. Napoleon, when with his army in Italy, was in the habit of employing fires, to a great extent, to keep away malaria; and he did it with great success.<sup>f</sup> But here the heat must have been useful, by dissipating moisture and cold. Dr. Lind mentions,<sup>g</sup> that when the Edgar ship of war was off the coast of Guinea, in 1765, the crew were very sickly, and many of them died from fevers of this description; but in the crew of a sloop of war which always accompanied her, very few were ill, and none died. In the latter there was a fire

<sup>e</sup> This is mentioned by Sir Gilbert Blane on the authority of Mr. Astle, Keeper of the Records in the Tower, in the fourth volume of the Medico-Chirurgical Transactions, Page 101.

<sup>f</sup> See Dr. Macculloch's “Malaria,” Page 286.

<sup>g</sup> At Page 150 (Second Edition) of his “Essay on Diseases incidental to Europeans in Hot Climates.” (Part I; Chapter 4; Section 3.)

for cooking, on the same deck where the men lay, and which filled with smoke the spot where they slept, whereas in the *Edgar*, from the particular arrangement of the vessel, there was no smoke whatever between the decks. Here were two ships off a country which afforded a vast quantity of malaria. The crew of the one remained healthy; and that of the other became diseased, in the way I have stated; although the only difference between them was, that in the former the part where the men slept was constantly, or almost constantly, filled with smoke.

*Ague not Contagious.*—It appears quite certain, that intermittent and remittent fevers are not contagious; though formerly ague was considered to be so. Dr. Fordyce, who was almost one of our own day, says (both from his own knowledge, and a reference to the opinion of others) that ague is contagious. Dr. Cleghorn, in his work on the Diseases of Minorca,<sup>a</sup> says the same. Dr. Wells, a colleague of Dr. Fordyce at St. Thomas's Hospital, accounts for the opinions of the latter by remarking, that he (Dr. Fordyce) fancied, that *continued* and *intermittent* fevers were mere varieties of the same disease; and as it appeared, in those days, that continued fever was contagious, so he was obliged to maintain that *ague* was contagious. Dr. Cleghorn's mistake is supposed to have arisen from his having observed, that most of those who were about the sick, in Minorca, had the disease;—forgetting that it did not arise in consequence of emanations from the sick, but from the situation in which they were placed. It is no proof whatever that a disease is contagious, that it is caught from going to see a person labouring under it; for he may be in the very spot where he contracted it, from local circumstances; and in going to him, we go to the spot which has given *him* the disease; and which may therefore give it to *us*. In order to prove that a disease is contagious, there should be a sufficient number of instances of persons going from the place where they contracted the disease, to a healthy part; and there giving it to others. There is no reason whatever to suppose that agues are contagious; though, formerly, not only were *they* supposed to be contagious, but even *scurvy* was also pronounced to be communicable to others.<sup>b</sup>

*Chemical and Physical Qualities of Malaria.*—The chemical nature of malaria, or marsh-miasmata, is unknown. It is not carburetted hydrogen; and no known chemical substance has the same effect. The air of marshes is said not to differ chemically from the air of any other part, with respect to its quantity of oxygen. There is no reason to suppose that it is a deficiency of oxygen, or an excess of carbon, or the presence of carburetted hydrogen, that renders the air pestiferous in this case.<sup>c</sup> It is said by De Lisle, that malaria has no smell. Thus much, however, is known;—these exhalations may be suspended by aqueous vapour. Indeed, it is said that they never rise but with some lighter body;—that they require to become so suspended, in order to rise at all. Being, however, suspended by aqueous vapour, they are even more deleterious than contagions; for, like contagion, a momentary application is sufficient, in many cases, to produce the disease; and, unlike contagion, they may be wafted, and produce their effect at a very great distance; whereas contagion spreads but a very short way, and after a certain distance is destroyed. Malaria, like other gaseous bodies, very easily finds a barrier; so that,

<sup>a</sup> "Observations on the Epidemical Diseases of Minorca, from the year 1744 to 1749, by George Cleghorn, M. D."

<sup>b</sup> Dr. Brown ("Cyclopædia of Practical Medicine"), from the result of cases which have fallen under his observation, still entertains a suspicion of its contagious nature; and, in confirmation of this opinion, he adduces the following case, related by Bailly:—"A lady arrived in Paris with an intermittent fever, which she had contracted in the country, in a marshy situation. This fever was accompanied by violent vomitings, and other serious symptoms; which displayed themselves at every paroxysm, and forced me to give bark. Scarcely was she cured, when her husband, who had never quitted Paris, but who had had the imprudence not to keep himself apart from her during her illness, was struck with the same symptoms, and in a manner altogether similar."

<sup>c</sup> The accused gases have been carbonic acid, azote, hydro-carburetted gas, hydro-phosphuretted gas, hydro-sulphuretted gas, and even ammonia;—to say nothing of a yet undiscovered compound of azote and oxygen, called "septon."—"Malaria; by John Macculloch, M. D." Page 421.

in Italy, a gauze veil is said to be efficacious in preventing its effects upon the human body.<sup>a</sup> On this point I can only repeat what I have read.

[Many attempts have been made to arrive at a knowledge of the physical qualities of this agent. Moscati and Broschi examined the atmosphere—the former of some very insalubrious rice-fields, the latter of an unhealthy spot in the papal states; from which examination it appeared, that the vitiated air contained albuminous flocculi, somewhat viscid in appearance, but the nature of which was not understood; and that it possessed a certain weight;—as it did not appear to rise in the atmosphere, unless mingled with it by currents of air. All that is valuable on the constitution of the atmosphere of those places where ague is prevalent, may be summed up from the results of the extensive investigations made by M. Julia:—1. The air of these several situations contains the same principles, and in the same proportions, as the purest air of the most healthy situations. 2. Marsh-air contains a principle which eludes the test of the most delicate chemical reagents. 3. Though the nature of the noxious vapour is unknown, there is reason to believe that its pernicious effects depend on a form of vegetable and animal substance in a state of decay, or on a solution of these substances in air, or on the gases resulting from their decomposition. 4. Experiment has not yet demonstrated in marsh-air the existence of azotic gas, carburetted hydrogen, ammoniacal gas, or any of the gaseous products of decomposition; and if they are present in this vapour, their quantity is too small to be appreciated. Whatever its constitution or essence may be, it at any rate appears evident, that in order to its production there must be present a certain quantity of moisture, vegetable or animal matter in a partial state of decomposition, and a degree of temperature which cannot be termed “cold;” for we see that it prevails in districts where such conditions obtain:—in the extended estuaries of rivers; in swamps which pass, under the exhaling influence of the sun, into a comparative state of dryness; on the banks of rivers subject to floodings; and on low, flat sea-shores.<sup>b</sup>]

*Period of Incubation.*—If these exhalations be very strong, they may kill instantly. Many allow that fever may begin in half an hour after exposure. Occasionally the exhalations have been so intense, that labourers, in France and Italy, in breaking up the ground, have died on the spot. Other persons have been seized with giddiness, and some have even died on looking into a ditch, or a drain, around which aguish fevers prevailed. Persons who have been scarcely exposed to the deleterious exhalations, have been immediately seized with vertigo, vomiting, and syncope; and from that moment have had regular intermittent, or remittent fever. But usually their effect does not occur till a certain period has elapsed. In South Carolina it is said, that eight or ten days is the shortest time which elapses, between exposure and the appearance of the disease. The reason for so long an interval may be, that there is less heat there than in many other parts. Dr. Wells believes, that the autumnal agues of that country do not appear till spring;—that is to say, the agues seen in spring, are the result of exposure in the preceding autumn. He founds his opinion on the fact, that strangers visit South Carolina in the spring, with perfect impunity. Dr. Lind mentions having seen these fevers take place the very morning after exposure. Dr. Bancroft gives an instance of the disease occurring instantly; and then other cases, which did not take place for many (even for nine) months. Dr. Bancroft likewise ascribes the agues of spring to the previous autumn; because he has seen persons seized with ague, after they have returned to England from a warmer climate, where they had been exposed to miasmata; and they have experienced the disease at too early a period in the year, for it to have arisen from malaria at home. Probably, the earliness of the period at which ague occurs, is in proportion to the intensity of the heat, and to the quantity of moist vegetable matter. It is certainly very common, in England, for harvesters who have worked in aguish districts, and have been exposed to the exhalations in autumn,

<sup>a</sup> Dr. Macculloch's "Malaria;" Page 299.

<sup>b</sup> "Library of Medicine;" Volume I; Page 233.

not to be affected till the east wind blows, in the following spring. I have seen very many cases of persons, who have left an aguish part in perfect health, and have remained so for some time,—even for months; when by chance getting wet through, or being exposed to a cold damp wind, they have been seized with ague. Dr. Macculloch doubts these long intervals;<sup>a</sup> but I have seen them in too many instances, to entertain the least doubt whatever.

*Insusceptibility from Long Exposure.*—By habit, persons become rather insusceptible of the effects of these exhalations; by habit, they cease to have ague when exposed to malaria; or, if they do have it, it assumes a very mild character. This is very commonly observed, in what are called “the *pernicious* districts” of Italy, France, and Sicily; in which districts those persons, chiefly, are susceptible of its operation, in whom glandular disease has been induced. To show the effects of habit, I may mention, that General Monnet (a French officer) found that, in a malarious situation in Walcheren, there was only one-half the sickness in a regiment during the *second* year, that there had been during the *first*; and that during the *third* year his men remained at the place, there was no sickness whatever. The inhabitants of one marshy district, when they go to another, suffer less than strangers;—less than persons who go to a marshy district, from a place that was perfectly healthy. A physician<sup>b</sup> in my parish<sup>c</sup> used to relate a story, from his own knowledge, of a party going up the Thames; of which party only one lady caught an ague. She had always lived in Edinburgh;—a high, dry, healthy spot; while all the rest of the party were inhabitants of a malarious place.

Yet many persons, who have not been previously exposed to malaria, escape it as well as the Dutch, who have been accustomed to it. The Dutch, who live in the midst of it, will not allow it to be unhealthy;—exactly as a person of filthy habits, believes himself to be as clean as is necessary. Persons, although well-informed on these matters, will frequently, when they come to an unhealthy place, be obstinate, and act the part of mules; and many such have suffered for it. We find it stated in Captain Clapperton’s “Travels,”<sup>d</sup> that the Captain himself, Mr. Pearce, Dr. Morrison, and Mr. Houlton (a surgeon), while on an expedition in Africa, lay all night on the banks of a creek, when there was no occasion for it; and the next night they lay in a market-place, though there were houses enough for them to have entered. The following day, Captain Clapperton was seized with fever; Dr. Morrison was seized in two days more; Captain Pearce the next day. Lander, their servant, was seized next; Mr. Pearce and Dr. Morrison died soon; and Mr. Houlton and Captain Clapperton died ultimately. They were all warned of the dangers of thus exposing themselves. Every day affords instances of this awful obstinacy;—this total disregard of human life. Because the Dutch are obliged to have dykes and ditches in their own country, they have surrounded themselves with them, where there is not the least occasion, in the East Indies;—merely, I suppose, to be like their brother frogs at home.

But it is said, that one unhealthy place does not, by any means, *always* give indemnity to an individual who goes to another; and that a place to season an individual perfectly for another, must be situated between the tropics, and not have a cold winter. It is found, for example, that Gibraltar will not season a person for the West Indies; but then Gibraltar is not situated between the tropics. Such a seasoning as would render a person altogether insusceptible of the disease, can only be obtained between the tropics; where we can conceive malaria to be produced in

<sup>a</sup> I know not if physicians have fairly observed, that it may be later than twenty-four hours from the exposure to the cause.—“*Essay on Remittent and Intermittent Diseases; by John Macculloch, M. D.*” Volume 1; Page 237.

the most intense degree. It is also to be remembered, that when a person has once had ague, he is very liable to a return of it from a slight cause;—such as from the blowing of a cold, wet, east wind; or from getting wet through; or from being, in any way, thrown out of health. He is rendered liable to have the disease renewed from slight causes; but altogether he is much less sensible to the influence of malaria.

*Evil Effects of Malaria on the General Health.*—Whether persons, however, have had ague or not, if they be constantly exposed to malaria, the constitution is impaired. They acquire a dull heavy look, and are bloated, or they are emaciated, shrivelled, pale, sallow, and weak. Sir Gilbert Blane says, that the people residing at Walcheren were far less subject to aguish affections, than strangers; but that they all looked sickly. Yet these Dutchmen would not allow that their climate could be unhealthy; and when they saw one-half of the English sick, through their noxious climate, they would not allow that it arose from the filthy ditches; but ascribed it to errors of diet, and the bad habits of the English. The liver and spleen are much disposed to become diseased; and dropsy to supervene. In the worst valleys of Switzerland, poor persons are shrivelled; young persons look old; and middle-aged persons appear in the greatest state of decrepitude. In these valleys, there is always a great quantity of malaria pent up. Indeed, so great is the injury produced by malaria, that whereas the average of human life in England is fifty years, in Holland it is only twenty-five. In some parts of France, which are very pestiferous through the malaria, the greatest average age is twenty-two; while in some it is only twenty and eighteen;\* and in others it is only ten. In some parts of Africa, and the East and West Indies, the average is as low as this.

[The following passage from Dr. Macculloch's book on Malaria, depicts in fearful colours the effects of malaria on the physical, moral, and intellectual qualities of the body:—

“There is nothing in these pernicious countries more striking to a cursory traveller, than the appearance of age which occurs at a very early period of life. Even the children are frequently wrinkled; and, in France, in perhaps all the worst districts, a young woman, almost even before twenty, has the aspect of fifty; while, in men, the age of forty is equivalent to sixty in healthier countries,—both in appearance and vigour;—the very few who live to fifty, appearing to have arrived at the protracted term of fourscore. Of personal beauty in females, there appears to be little trace at any time; but whatever may have existed is rarely prolonged beyond seventeen. And the expression of countenance keeps pace with all else;—being that of unhappiness, stupidity, and apathy: an habitual melancholy which nothing can rouse, and an insensibility to almost every thing which operates on the feelings of mankind in general. A slow and languid speech, a similar languor in the walk and in all the actions, indicate equally the condition of the mind and of the body, in these wretched countries.

“The condition of the mental faculties, whether intellectual or moral, is scarcely less remarkable, while it is more interesting; and if there should appear any exaggeration as to some particulars, or should any special fact, as asserted, depend on collateral causes of another nature, the general bearing of the whole, as related of Italy and France, has been confirmed too often by remarks of a similar nature, made in America and elsewhere by very competent observers, to leave any doubt as to the leading circumstances.

“That apathy which was just noticed as expressed in the physiognomy, is a character which influences the whole conduct of these degraded and unfortunate beings;—often proceeding to such a degree, that they are scarcely elevated above the beasts, in point of feeling. Seeking solitude, shunning society and amusements alike, without affections, without interest in any thing, they make no exertions to better their condition;—not even to avoid the sources of danger which surround them, or to take the most common precautions that are pointed out; while, attached

\* See Dr. Macculloch's “Malaria;” Page 6.

to the soil (from habit or indolence rather than from regard), they will not be convinced of its nature or dangers;—fatalists in practice, and even in belief; and refusing to admit that there is any other lot in life than that which is their own.

“That the general intellectual faculties are degraded, is a universal remark; while, in many places, and very notably in the Maremma of Tuscany, it is observed that absolute idiotism is common. This circumstance might naturally be expected, from physiological considerations connected with the general influence which malaria exerts on the body. And that this condition is even propagated, seems fully proved;—so that a universal degeneracy of both mind and body, appears to be the certain lot of those races, which a combination of unfortunate circumstances has placed in countries, that seem to have been intended rather for the habitations of reptiles and insects, than for those of man.”<sup>a</sup>]

*Affects the Lower Animals.*—It is said that, in very unhealthy places, even brutes are known to suffer.<sup>b</sup> Dr. Macculloch says he heard that a dog, at Guernsey, had a tertian ague;<sup>c</sup> but whether this is correct, I will not pretend to say. He adds<sup>d</sup> that epizootic<sup>e</sup> diseases frequently prevail at the same time with marsh-fevers; and that, in St. Domingo, the dogs are always the first affected.<sup>f</sup>

Malaria is the constant scourge of the earth;—not the *occasional*, but the *constant* scourge. It produces not only fevers, but (very frequently) dysentery,<sup>g</sup> cholera,<sup>h</sup> and sometimes neuralgia;<sup>i</sup> and it causes an intermittent or remittent character to be given to other diseases. Even when it causes no positive disease, it undermines the health. Malaria abounds to a frightful extent in Greece, Italy, France, America, Asia, and Africa.<sup>j</sup> We know nothing of it here, compared with the violence of its ravages in those parts.

*Extent of its Ravages in England.*—It was once far more injurious in this country than it is now; but, from the energy and industry of the English character, such extraordinary improvements have been made in every thing to promote the well-being of man, that nothing abroad can be compared with our advantages. Southwark was once an entire swamp; and at Westminster there is a toll-gate, called the “Marsh-Gate;”—from being situated in a place where formerly (and not very long ago) there was a marsh. From the improvements that have been made, however, ague is now comparatively rare in London. It prevailed to a great extent before the fire of London, in 1666; but from that time the place was better drained;—so that the fire did good. Before the fire, ague raged like a plague. Between 1667 and 1692, no less than two thousand persons died in London of dysentery;<sup>k</sup>—arising, no doubt, from the same cause as ague. So great, however, has been the reduction, that in 1728 there were only forty-four deaths from ague; in 1730, only sixteen; and in the bills of mortality for the first ten years of the present century, there are recorded only four deaths from ague. Within the last five or six years, agues have increased through the country, and in London; and this may be easily explained. They have not increased to what they were formerly; but still there has been an increase. Sydenham says that they disappeared in London from 1674 to 1678; and they disappeared in Plymouth (Huxham says)<sup>l</sup>

from 1755 to 1760. They were absent from Portsmouth for three or four years. They returned again in London epidemically in 1751, 1753, and 1754. Sydenham says that they returned again from 1677 to 1688; and they also prevailed at the beginning of the last century. These are all accidental occurrences. It has been said by Dr. M'Michael, of the Middlesex Hospital, that during the few years that ague prevailed so much, the average heat was greater than when it disappeared. The heat being greater, of course there was more vegetable decomposition. To show the increase of late, I may mention that in 1823 I had but eight cases of ague; in 1824, I had fourteen cases; in 1825, fifteen cases; in 1826, forty-four cases; in 1827, fifty-three cases. The number then declined; so that in 1828 I had twenty-seven cases; and in 1829 I had only eight. If we had accurate accounts, we should perhaps find that when ague increased in former times, the average heat was higher than usual;—just as it has been observed to be by Dr. M'Michael, during the last few years that ague has become prevalent again.

*It gives to Other Diseases an Intermittent Type.*—Persons who have once had ague, or who have it upon them, are much disposed to exhibit a more or less aguish form of any other disease under which they may labour;—that is to say, when a person is the subject of ague, it is very common for diseases to become more or less intermittent; and this is especially noticed in aguish counties. Rheumatism, ophthalmia, vomiting, and purging, may all be intermittent, and even periodical. However, it is quite certain that, independently of malaria, many diseases will become intermittent. Insanity is sometimes intermittent. I have seen a person mad once a-year, or once in three years. Palsy is likewise occasionally intermittent; and in one case I saw it periodical. It came at a particular hour in the day; but the patient had had ague, many years before. Dr. Macculloch, however, ascribes a vast number of diseases to malaria;<sup>a</sup> but I think there cannot be a doubt in any one's mind but his own, that he has carried his ideas to an extravagant pitch. He has done great good by attracting the attention of persons to malaria, more than it was before; and his writings are very powerful and learned; but I think no one can read his publications without perceiving, that he had one idea constantly before him.<sup>b</sup> That idea was *malaria*; and he ascribes infinitely more to it than reason can justify. But although I am satisfied of the extravagant length to which he pursues his ideas, yet I am equally satisfied that too often we do not ascribe diseases to malaria, when they really arise from that source. We frequently meet with sporadic cases even of ague, which cannot be easily traced to malaria; but I have no doubt that, if we could ascertain all the circumstances, we should find that the individual has a striking tendency to it; and has been exposed to malaria by passing through a market, or some other place, in which there was vegetable matter in a state of decay. It is also to be remembered, that though the influence of malaria is so great, yet cold and wet, and other causes of debility, will induce ague, without the reapplication of malaria, when a person has once had it. Sometimes, too, when malaria has been applied, the disease does not occur till such circumstances as these have taken place. I mentioned,<sup>c</sup> in my introductory re-

<sup>a</sup> These diseases are ague, dysentery, cholera, headache, vertigo, tic-douloureux, rheumatism of the face, neuralgic ophthalmia, neuralgic affections of all parts of the body, dyspepsia, and derangements of the liver and spleen. See Dr. Macculloch's Volumes on "Marsh-Fever and Neuralgia;" and Chapter 10 of his "Malaria;" (Pages 419 to 427). At the end of the former work, there is a systematically arranged table of the various diseases said to be produced by the poison in question.

<sup>b</sup> If the sword has slain its thousands, malaria has slain its tens of thousands. It is disease, not the field of action, which digs the grave of armies; it is malaria by which the burning spirit, fitted for better things, is quenched, and in the coward's bed of death. This is the destroying angel,—the real pestilence which walks at noonday; and to which all the other causes of mortality are but as feeble auxiliaries in the work of destruction. This is malaria;—the neglected subject to which I am desirous of calling attention; in order that, by this attention, its powers may be diminished: malaria, from which even ourselves, here in England, are not free; though, from ignorance, unaware of it; or, from unwillingness to receive conviction, shutting our eyes to the truth.—"*Malaria*," by John Macculloch, M. D." Pages 8 and 9.

<sup>c</sup> See Page 45.

marks, that the *predisposing* will sometimes become the *exciting* cause. The exciting cause of ague is (unquestionably) malaria; but sometimes it will only act as a *predisposing* cause; for it will lie dormant in the system till the person gets wet through;—in which case the latter is really the exciting cause. From all the circumstances, I am convinced that many cases are aguish, where there is no suspicion of their true nature.

### c. Proximate Cause.

The proximate cause of ague—the real essence of that state which is always present when the symptoms occur—is unknown. We can say, with certainty, that it is a peculiar state; for a person, in the intermission of ague, is perfectly well. There is frequently no disease to be found, whether inflammatory or otherwise, of any particular organ. Again: ague frequently cannot be removed by antiphlogistic measures; though occasionally it certainly may: as well as by any thing, in fact, which makes an impression on the system. Again: inflammatory diseases are not cured by sulphate of quinine, and remedies of that description. The disease *may* be inflammatory, and often *is* so; and requires antiphlogistic measures; but its *essence* is not inflammatory;—at least, I know no proof of it. It may be inflammatory; but there must be something more than inflammation.

*Curative Influence of certain Remedies.*—It is impossible to say how it is cured by the measures which are specifics in the disease;—as, for instance, bark. It cannot be by curing inflammation; neither can it be by irritating the stomach. Some have affirmed that bark only acts by irritating the stomach; but if that were the case, brandy and cayenne-pepper would do just as well; and so would corrosive sublimate. Nor can I conceive that specifics operate by strengthening the patient. We might give a person full diet, and take care that he has regular exercise, and improve his strength in every way we can; yet we should not cure his ague; whereas a few grains of quinine,<sup>a</sup>—a quantity too small to strengthen the body directly,—continually puts a stop to it. I cannot pretend to say how it is that remedies act in curing the disease; but of this I am satisfied, that it is not what people pretend it to be. The remedies do not cure it, as people allege, by strengthening, or by stimulating, or by any similar operation. We can only say there is a peculiar state; and that remedies cure it by a peculiar operation. This is, I acknowledge, saying nothing; but, at any rate, it is not advancing unfounded hypotheses; and fancying ourselves wise, when we are really ignorant. Arsenic, which cures ague very well, is not a tonic. It will debilitate the body, cause it to tremble, and depress the powers of the system; and yet a small quantity will stop the disease. Why a remedy of this sort is called a tonic, I do not know.

*State of the Blood.*—[In those fevers which arise from marsh-miasmata or contagion, it is an opinion held by Dr. Stevens, and supported at great length in his work on the blood, that a diseased condition of that fluid is the first in the train of symptoms which occur, and the immediate cause of those which follow. “The blood itself,” says Dr. Stevens, “is both black and diseased, even before the attack. During the cold stage, it is very dark. When first drawn, it has a peculiar smell; and it coagulates, almost invariably, without any crust. There are black spots on the surface of the crassamentum; the coagulum is so soft, it can easily be separated by the fingers; and, during its formation, a large quantity of the black colouring matter falls to the bottom of the cup. In the hot stage, it becomes more red; and, in some cases, it is even florid for a time; but, during the remission, it is darker in colour than healthy blood, and decidedly diseased in all its properties.” In milder cases, the blood which is drawn may coagulate without a crust on the surface; but in the more severe forms of this affection, when the blood was drawn at an advanced period of the disease, a part of the albumen coagulated on the surface of the fibrin, and formed a diseased mass, which in ap-

<sup>a</sup> From “quinquina,” the name given by the French to Peruvian Bark.

pearance had a greater resemblance to oatmeal-gruel, than to healthy blood. The serum which separated was also diseased; it had a brownish colour, and in some cases an oily appearance; which is never met with in the clear serum of healthy blood."<sup>a</sup>]

*Cause of Intermittence.*—[Intermittence, so far as we yet know, is an unexplained pathological fact. Among the various hypotheses that have been offered on the subject, the most ingenious and inductive in its nature, is that which has been proposed by M. Bailly. He first observes that, in situations and seasons in which intermittents affect the human species epidemically, epizootiës reign among the lower animals; but, however their symptoms may vary in other respects, in one point they all agree,—that of being strictly continued;—intermittence being never observed in the diseases of brutes. He then points to the mode in which the various actions of life are performed in man and the lower animals. During the whole of their existence, the lower animals preserve, in all the operations of life, the same horizontal position; and, consequently, the heart, abdominal viscera, and brain, retain the same relative position to each other; but man, on the contrary, changes from the vertical to the horizontal position; and consequently each *nycthemeron*<sup>b</sup> (period of one day and night) presents a succession of sanguineous congestions, which are felt according as he is in the erect or horizontal posture, and according as the viscera change their relative position. These varying congestions constitute the physiological condition of most healthy persons; but, argues M. Bailly, every pathological or morbid state is only the exaggeration of a physiological or natural one. The sanguineous congestion of the digestive organs, displays itself in a degree which may be considered morbid in females or other delicate persons; who are either sick on first assuming the erect posture in the morning, or feel a total inaptitude for any occupation till they have taken food; and is well illustrated by that febricula, first described by Roederer and Wagler, which may be said to constitute the habitual state of many literary and other sedentary men. M. Bailly attributes this disorder to gastro-enteritic irritation, produced by the erect position acting on a delicate and sensitive frame; and considers that the horizontal posture diminishes it;—so that if the patient remain so long in this posture as to bring this irritation to the lowest point, the functions of the skin are then restored, and the indisposition is removed temporarily by a crisis. MM. Roederer and Wagler have observed, that nothing tends so much to the production of intermittent fever in this delicate class of persons, as the suppression of these morning perspirations. What has been described above, which is in some degree pathological, is but an excess of what exists in all individuals, and intermittent fever is but a further grade of such an excess; or, as Bailly expresses it, is the exaggeration of that assemblage of organic acts, which completes a *nycthemeron*; and which takes place in the following manner:—1. Morning congestion of the stomach and intestines. 2. Augmentation of the different nervous influences which it produces throughout the system; and which, according to the particular disposition of the individual, gives rise to one set of nervous symptoms rather than another; or which excites that part of the nervous system which penetrates all our organs, accompanied by blood-vessels, when intermittent fever takes place. 3. Cessation of this congestion by the horizontal posture.

The chief objections to this very ingenious hypothesis are:—1. It is based on the assumption that the cause of ague exists in the alimentary canal; which, in the present state of our knowledge, is doubtful. 2. While it provides an explanation for the occurrence of quotidian ague, tertians and quartans are still unexplained; which are considerable lacunæ in the hypothesis. c]

## SECTION IV.—DIAGNOSIS AND PROGNOSIS.

The affections from which it is necessary to distinguish intermittent fever, are hectic, remittent fever, suppuration, stricture, and retention of urine.

*Hectic.*—In the diagnosis, we sometimes have a little difficulty in distinguishing ague from hectic. Hectic is a disease which continues for a length of time; and so may ague. It is called "hectic," from being placed in the habit (ἔξῃς);—being a *continued* disease; that is to say, lasting for a length of time. It also resembles ague in another respect;—it is more or less intermittent. In hectic, however, the rigors are irregular. All the stages, too, are irregular;—one comes before the other, without any sort of order. After a time, in hectic, there are no rigors;—nothing but sweating, constant feverishness, and a quick pulse; and this feverishness is excited by taking food, and by the slightest quantity of nourishment. There is generally profuse sweating on dropping asleep;—the moment the patient drops asleep, some part of the body is in a sweat. In ague, when the sweating is over, the person is comparatively well; but in hectic, so far from being better, the patient feels weaker. In hectic, there is a red patch on the face, the palms of the hands, and the soles of the feet; the tongue is moist, and generally red. In the urine there is not the lateritious, red, brick-dust sediment of fever; but a pink deposit. In hectic, there is not the exposure to the cause of ague; and there is not the aguish face;—that peculiar cast of countenance, which is so often seen in ague. In hectic, there is frequently a local disease;—suppuration in some part of the body; and there is an exacerbation at night, and frequently at noon. No one of these symptoms alone, will enable us to distinguish the disease; because ague is sometimes irregular,—recurs at no certain time; and is, perhaps, even almost *remittent*; so that we may have to make the distinction between *intermittent* and *remittent* fever. In ague, we may sometimes have profuse sweating, and little else. It is therefore necessary, in making a diagnosis, to take all these circumstances into consideration; and, by so doing, we shall (in ninety-nine cases out of a hundred) be correct.

*Ague and Hectic together.*—Now and then, however, there may be a little difficulty. Sometimes ague and hectic occur together. I have seen hectic in a person labouring under phthisis;—where there were rigors, increased heat, and sweating, from ague; and increased heat and sweating from the suppuration; so that really the case was one of difficulty. There was at the same time the aguish face; so that it would have been difficult to make the distinction between the diseases, had I not known there was suppuration in the lungs. The aguish face, and the circumstance of having been exposed to the cause of ague, showed that probably ague was present; but the suppuration also showed that hectic fever was present. If we take pains with our cases, we can rarely be deceived. Now and then there will be a difficulty; but that will occur in instances where the hectic fever is attended by great rigors; or where, on the other hand, ague is assuming a *remittent*, rather than an *intermittent* character; and the patient has a local affection.

*Nervous Debility.*—We must also remember that rigors will occur without ague or hectic. Many persons, from mere nervous debility, will experience rigors;—they will not be able to do their business, and their teeth will chatter, merely from depression of mind.

*Stricture.*—Again: persons with a stricture are subject to rigors. Some persons always have rigors when a bougie is passed; and without that, simply from a stricture in the urethra, many will experience the same. If we find the rigors come on suddenly, and there is a stricture in the urethra, we ought to doubt whether there is ague. When rigors occur from stricture, or some other disease of the urethra, there is generally no heat or sweating. Neither is there the aguish countenance; nor can we ascertain that the individual has been exposed to malaria. If, however, there should still be a doubt, after all our inquiries, it is best in all cases to give the remedies for ague. If they be properly managed, they can do no harm;—at any rate the sulphate of quinine can do none.

The diagnosis of *intermittent* from *remittent* fever, is an easy matter. It is a mere circumstance of degree. If there be a *perfect* intermission, we call it "ague;" if it be *imperfect*, we call it "remittent fever."

*Suppuration*.—[The danger of an error in diagnosis is still greater, when deep-seated and undetected suppuration has taken place. The paroxysms of fever are such as, for a time, to impose on the most experienced. In cases of intermittent fever, therefore, it is well to examine for visceral disease, especially in districts little liable to ague; and to bear in mind that, even in the midst of endemic ague, we may have cases resembling intermittent fever, though, in fact, of a totally different nature.<sup>a</sup>]

*Prognosis*.—The prognosis in ague, in this country, is almost always favourable. We may almost always promise a speedy cure. If there be conjoined with the ague a local structural disease, of course that part of the prognosis must stand on its own foundation; but the ague itself we may generally cure. If its type be quartan, we cannot promise so speedy a cure, as if it be tertian or quotidian; and I believe we are placed under the same restrictions, if the disease be autumnal and not vernal. An autumnal ague does not yield so readily as a vernal ague; and, indeed, the latter usually yields so easily, that it often ceases spontaneously, after a few paroxysms;—some think after seven. It generally ceases when the warm weather comes in; and will frequently do so on a person changing his residence. It is the ague of *spring*, and not of *autumn*, that is "fit for a king."<sup>b</sup> There is a contrary proverb for *autumnal* ague:—

"Febris autumnalis  
Est longa aut letalis."<sup>c</sup>

In hot climates, and even in England, many *intermittent* fevers become *remittent*; and from being remittent they will become *continued*, unless vigorous measures are adopted; and may prove rapidly fatal, by congestion of the head, thorax, or abdomen. It is in hot countries, and in hot weather in this country, that we have to give a guarded prognosis. In hot countries it is common for patients to die early in the attack;—in consequence of the enormous congestion which occurs in the head, chest, or abdomen. Now and then this may be the case here, from some peculiarity in an epidemic. We have always to consider, therefore, in giving a prognosis, whether there is any peculiar form of ague present; and if that be the case, and if it be a form that is sometimes fatal, our prognosis must be more or less guarded; although, without that, we should give the usual prognosis. We have no idea, in this country, of what aguish fever, remittent or intermittent, is in hot climates. In Italy, they are called "*pernicious* fevers;" for as soon as a person is seized, he may fall into a comatose state, from which he never recovers; and, on inspection after death, the greatest degree of congestion is found in the lungs and head, and also in the abdominal viscera. In this country, however, we may almost always promise, not only a *cure*, but a *speedy* cure; and that by means not at all severe;—"tuto, cito, et jucunde."<sup>d</sup>

## SECTION V.—TREATMENT.

The means which we employ for the purpose of curing intermittent fever, may be divided into those which are had recourse to in the *intermission* of the disease, and those which are employed during the *paroxysm*. With regard to the latter, the greater number of them are adopted rather with a view to the temporary *allevi-*

<sup>a</sup> "Principles of the Theory and Practice of Medicine; by Marshall Hall, M. D." Page 134.

<sup>b</sup> See Page 242.

<sup>c</sup> "An autumnal fever is either long continued or fatal."

<sup>d</sup> "Asclepiades officium esse medici dicit, ut tuto, ut celeriter, ut jucunde curet.—*Celsus; Liber 3; Caput 1.* ("Asclepiades lays it down, as the duty of a physician, that he should effect a cure safely, speedily and pleasantly.")

ation, than to the cure of the affection; and I need not say that they must be very different, according to the stage in which they are employed.

### a. During the Paroxysm.

*Cold Stage. Warmth.*—In the cold stage, common sense would point out that there should be plenty of covering, and warm drinks; and some have recourse to the warm-bath. It would, however, I conceive, be better to employ dry heat; for warm air may be easily and instantly conveyed to a patient when in bed, by having something under the clothes to raise them, and a tube continued from above a spirit-lamp. Thus we surround the patient with hot air, in any quantity we please, and of any temperature. Something like an inverted funnel is placed near the bed, with a spirit-lamp under it; a tube goes from the extremity of this funnel-shaped body, and is conveyed under the bed-clothes; so that the air is dispersed throughout the bed. The degree of heat may be regulated, by altering the proximity of the lamp to the funnel. This will be found to be by far the best mode of applying heat externally;\* and on this account, particularly;—that when we employ vapour, the patient, for the most part, must be in a sitting posture; or at any rate must be taken out of bed, and more or less exposed after the bath. But, in extreme exhaustion, it is a material thing to avoid all this, and to keep the person horizontal; and by using the contrivance I have mentioned, we need not take him out of bed, or remove him from the horizontal posture. Heat may thus be employed, to an extent sufficient thoroughly to warm the surface; and friction, especially to the extremities, may be had recourse to at the same time;—just as grooms rub shivering horses on the legs, and even on the ears. If it be right to apply heat, during the intensity of the cold stage of intermittent fever, I imagine that this contrivance will be found much better, than a bath either of hot water or of vapour.

*Warm Drinks.*—Warm liquids, of course, appear to be indicated; but we should guard against administering real stimulants. It is very well to apply caloric by means of hot liquids; but by giving stimuli (such as brandy and wine) we incur the risk of doing more than was intended;—of increasing the subsequent hot stage; of inducing delirium, and causing congestion and inflammation of the head, and internal organs. I should therefore give hot diluents, or at the utmost hot *spiced* diluents, rather than alcohol, or things which are in themselves *real* and *permanent* stimulants.

*Bleeding in the Cold Stage.*—A remedy has lately been recommended, which one could not *à priori* imagine to be proper; but in favour of which there is very strong testimony. I allude to the abstraction of blood. The best information upon this subject, is to be found in Dr. Mackintosh's "Practice of Physic."<sup>b</sup> I believe he is the gentleman who first advised, and put in practice, this mode of treatment. In the cold stage of fever, the circulation is greatly deranged. The internal parts are in a state of congestion; the head, lungs, heart, and all the organs the veins of which go to form the "vena portæ," as well as that vein itself, and its divisions, are in a state of extreme turgescence; and, by removing a certain quantity of blood, we unquestionably diminish this load. We give ease to nature; and it is found that the loss even of a small quantity of blood, relieves more or less the general uneasiness of the patient. I mentioned<sup>c</sup> that, in hot countries,—where they have what are called "*pernicious* fevers,"—it is very common for those fevers to be attended by such a degree of congestion, as we rarely see in this country;—congestion which speedily proves fatal, and it must therefore be a very great point,

\* In the Cholera-Hospital at Edinburgh, every bed was furnished with a hollow "tin mattress," (as it was called); which could, at any time, be filled with steam, by means of a pipe which communicated with a boiler.

<sup>b</sup> "Principles of Pathology and Practice of Physic. By John Mackintosh, M. D." Fourth Edition. See also two papers published by him, in Volumes 27, Page 269, and 28, Page 276, of the "Edinburgh Medical and Surgical Journal."

<sup>c</sup> See Page 269.

in hot countries, to bleed as early as possible. Dr. Mackintosh mentions, that the cold stage is shortened by this practice; that the hot stage is either prevented, or diminished in violence and duration; and that many cases are entirely cured. A report on this subject by Dr. Stokes, will be found in the "Edinburgh Medical and Surgical Journal," for January, 1829.\* It is not altogether favourable. He says that venesection is more or less useless, and more or less injurious, in different respects. He says it is beneficial in removing the local symptoms,—in removing the symptoms of congestion about the chest and abdomen;—which is just what we should imagine. But (he says) he was always compelled to exhibit quinine sooner or later; and he adds,—as a reason for limiting venesection to those cases where there is coma or inflammation,—that a friend has informed him of some patients, so treated, who never recovered. There can be no doubt, I think, that the practice is not so injurious as one would (perhaps) imagine beforehand; but that, on the contrary, it frequently does a great deal of good; for it removes the local symptoms, frequently shortens the complaint, and sometimes cures it. As far as I can understand, it is, for the most part, rather a means of *alleviation*, than of *cure*; but I have no doubt that, in many cases abroad, where the congestion is extreme, it is imperiously necessary. I have never myself had recourse to it; and therefore cannot speak of it, except as a matter of opinion. I put the testimony of others together, and infer for myself; but I have no facts to give. I have never seen a case of ague, which I thought required such treatment. I never saw a case which I could not cure by the sulphate of quinine; and knowing this, and not seeing any violent local symptoms during the cold stage, to make such treatment necessary, of course I have never employed it.

Speaking of venesection in general, and not of the cold stage in particular, Dr. Lind says that he, and two others, had each three patients with ague. Each bled his three patients; and each lost one.<sup>b</sup> This, however, is saying very little, unless we knew the particulars of the cases. Dr. Mackintosh says that it is always safe, often shortens, and sometimes cures; but, finding that I can always remedy the affection by the sulphate of quinine, in some quantity or other, I have not thought it right to take away blood, and thus impair the powers of the patient. There can be no doubt, however, that it is a remedy to which it is our duty to have recourse, if we find great symptoms of congestion; and if we fear that the next attack will prove fatal.

*Opium in the Cold Stage.*—Opium is found both to shorten and to alleviate the cold stage. I have given it with very great success. The best authors tell us, that a full dose of opium certainly shortens this stage, and always alleviates it; but still, if I found great congestion of the head, or of other parts, I would certainly order bleeding, in preference to opium. A tourniquet<sup>c</sup> has sometimes been applied to an extremity, for the purpose of producing early excitement. One would conceive that, by this means, internal congestion must be increased. If we compress the femoral<sup>d</sup> or brachial<sup>e</sup> artery, there must be a larger quantity of blood thrown upon other parts; and if such a remedy does good, it must be by producing such a load, as will stir up nature to attempt its removal;—so that the body will be hurried out of the cold stage, more quickly than it would otherwise have been.

*Hot Stage.*—When the *hot* stage comes, we have to give cool drinks; to take off some of the clothes; and to employ, if it be necessary and advisable, the tepid-bath; or warm affusion, or warm ablution. There would, I should think, be no harm in *cold* affusion, or *cold* ablution; neither should I hesitate to bleed in the hot stage, if there were any congestion, or any inflammation. A cure has now and then been effected in the hot stage, by a person jumping into a pond (which is a

<sup>d</sup> From "*femur*, *femoris*," the *thigh*.

<sup>e</sup> From *βραχιον*, the *arm*.

cold-bath); but I believe this is rather a dangerous practice. Opium, in this stage, has likewise been found of use. Dr. Lind says that he found opium useful in the hot stage; both in shortening its duration, and mitigating its violence. It would appear, then, that venesection is admissible in the *cold* stage, as well as in the *hot*; and that opium does good in both stages.

*Sweating Stage.*—When the *sweating* stage has arrived, all is going on well, and the paroxysm is nearly at an end; and then (if the patient chooses) we give him warm diluents; and put on more clothes than in the hot stage, because he is gradually cooling. We must not allow a draught to blow upon him; but we may attempt to lessen the duration of the sweating stage (which will sometimes run on for many hours) by diminishing the quantity of clothes, and cooling him gradually. We must be very cautious, however. In the *hot* stage there is no danger, I presume, from tepid ablutio; but in the *sweating* stage we must be more on our guard. In this stage narcotics, and every thing that debilitates, would be wrong. Nature is now exhausted, and wants repose; and to lower her still more, must be not only injurious but unnecessary; because health is about to be restored, and things are now nearly at a conclusion. If the patient be exceedingly faint, stimulants may be given; but before we exhibit them, we must take care to observe whether local congestion, or inflammation, may not be present.

#### b. During the Intermission.

The great means, however, for curing the disease, (unless venesection be considered a very important means,) are certainly to be employed in the *intermission*. By the term "*intermission*," we mean the period between the paroxysms; while by "*interval*," we mean the period of the paroxysm and the period of intermission together. The two chief remedies, in the cure of this disease, are bark and arsenic.

*History of Bark as a Remedy for Ague.*—Nothing is more instructive, in pointing out the impropriety of hastily deciding against a medicine, than the history of bark. Peruvian bark was first brought from South America in the year 1632; but the mode in which its efficacy was discovered, has not been well ascertained. So highly, however, was it thought of at first, that in the year 1658, sixty florins\* were given for twenty doses. It was then made a nostrum of, as all good medicines are; till at length many regular practitioners wrote against it; and such was the prejudice excited, that, about thirty years afterwards, several hundred pounds' weight of it lay at Piura, unable to find a purchaser. An alderman died, while using it to cure his ague; and it was therefore immediately asserted, that he was killed by it. Oliver Cromwell, who (as I before stated<sup>b</sup>) had an ague, was not allowed to take bark; and consequently died of the affection. The prejudice against it continued to extend, and great violence was manifested. Sydenham, however, though at first opposed to it, gave it boldly; and warmly advocated its employment. Violent medical altercations took place;—far greater than any which now occur; and those who employed it were called "murderers," and were stigmatized as being unfit to practise. Sydenham gave it in larger doses than his contemporaries; and exhibited it, not during the paroxysm, but in the intermission. Now there can be no doubt that it may do harm during the paroxysm; for it may overload the stomach, and increase congestion, if given in large quantities. Sydenham, therefore, introduced a great improvement, by giving it in the intermission; and he improved its efficacy by giving it in large doses. The efficacy of many medicines is not properly ascertained, in consequence of their not being given in sufficiently large doses. Many persons will exhibit a medicine; and, if it does not appear to answer, relinquish it immediately;—without determining whether it will really do good or not. Sydenham—by giving larger doses than his contempo-

\* Presuming that the *Spanish* florin is meant, this sum will amount to about thirteen pounds sterling.

<sup>b</sup> See Page 243.

ries, by exhibiting it between the paroxysms, and by gradually increasing the dose—found that it deserved all the praise which had been bestowed upon it.

*Dose of Bark.*—When it does not cure the disease as rapidly as we could wish, it should be given in the largest dose that the patient will bear. A drachm or two drachms every two hours, is frequently necessary to cure the affection. Dr. Gregory<sup>a</sup> used to tell us he was informed by a practitioner, that a friend of his, in the delirium of ague, took from three to four ounces of bark; and not only did no ill effect ensue, but he was cured from that moment. It ought to be given finely powdered; because, if it be not, a very small quantity only will come in contact with the stomach and intestines; and its full virtue is not obtained.

*Varieties of Bark.*—There are three kinds of Peruvian bark;—the yellow, the pale, and the red.<sup>b</sup> The latter is preferred by many, as being the most powerful; but although the most powerful, it is not so well borne by the stomach. Dr. Chapman (of New York<sup>c</sup>), Dr. Sanders (who practised at Guy's Hospital<sup>d</sup>), Dr. Rigby (of Norwich<sup>e</sup>), and Dr. Skeete,<sup>f</sup> all wrote on the red bark; and extolled it as being more efficacious than the others.

*Mode of administering Bark.*—Milk is one of the best vehicles in which bark can be given. Some give the powder in decoction, and some give it as an electuary; and it may be given thoroughly mixed with any syrup or sweet substance, and then diffused in some liquid,—so as to be drunk. Sometimes it disagrees with the stomach; and therefore it is necessary to add something to it. Many persons, from pure bark, experience nausea, and perhaps vomiting; while, in some, it occasions purging. In all such cases, a few drops of tincture of opium, will frequently enable the stomach and intestines to bear it. If it be only the stomach which is disturbed, an effervescing draught will answer the purpose; and so will prussic acid. A small quantity of prussic acid, given at intervals in the course of the day, will enable the stomach to bear bark, and many other things, very well. But if the intestines be deranged at the same time, opium is probably one of the best things; because neither an effervescing draught, nor prussic acid, will lessen the purging. We may sometimes bring a patient to bear bark by degrees;—giving him small doses, and increasing them. In the case of children, it may be given in the form of clysters; and some persons have been cured, it is said, by its external application;—by having it tied, in fine muslin, or fine linen, on different parts of the body. I recollect hearing Sir Henry Hallford say that, when he was a child, he had ague; of which he was cured by wearing a jacket of bark. A double jacket was filled with powdered bark, and put next his skin.

*Active Principles of Bark.*—It is now ascertained that the power of Peruvian bark resides in two substances, called “*quinina*” and “*cinchonina*,”<sup>g</sup> and of

<sup>a</sup> See Note to Page 239.

<sup>b</sup> Ascribed to “*Cinchona Cordifolia*,” “*Cinchona Lancifolia*,” and “*Cinchona Oblongifolia*,” respectively. But although the Pharmacopœias of London, Edinburgh, and Dublin, all agree in this respect, Dr. Duncan observes that there is no satisfactory evidence of their being right;—“on the contrary, it is almost certain that, with regard to some of the species, they are wrong.” Some highly instructive observations on this subject, distinguished by all his usual acumen, and never-tiring patience of investigation, will be found in his “*Edinburgh New Dispensatory*,” Pages 372 to 387 (twelfth edition). A very complete account of the different kinds of Cinchona Bark, is given by Mr. Pereira; whose Lectures on Pharmacology, unrivalled for extent and accuracy, were inserted in the “*London Medical Gazette*” (Volumes 17 to 20); and were afterwards published in a separate form. Those who consult the interesting lectures of Dr. Sigmond, published in the “*Lancet*” for 1836-7 and 1837-8, will see what the graces of a polished style, and illustrations collected from every department of literature, can do for a subject usually considered so dry and unattractive as Materia Medica.

<sup>g</sup> All the additional alkaline bodies have so lately come to light, that their names are not yet settled. The French terminate their appellations in “*ine*,” as, for example, “*morphine*,”

these two the former is chiefly used; and that in the form of sulphate. It is found by chemists, that both these substances abound most in the red bark; and we therefore see how it is that the red bark was supposed, by many, to be the most efficacious of the three kinds. Quinina is said to abound most in the yellow bark,—the "*cinchona cordifolia*;" and the cinchonina in the pale bark,—the "*cinchona lancifolia*." I have given the quinina, both simple and in the form of sulphate; and have cured ague with it very well; but I have never employed the cinchonina.<sup>a</sup>

"brucine," "strychnine," &c.; but, for the sake of uniformity with the names of the old alkalies, the termination should be "*a*," and it seems to me most eligible to adopt the French appellations, with the change of the final *e* into *a*;—for example, "morphina," "brucina," "strychnina," &c. Some have proposed to designate "quinina," "quina," or "kina;" but the latter, at least, is too similar to the word "*kino*," and would, besides, lead any one to suppose the substance it denotes must be the basis of kinic acid;—another instance, I may remark, of objectionable nomenclature; from the circumstance of a very different article being termed "*kino*." "Cinchonina" is, by some, called "cinchonina;" but the word is evidently too similar to "*cinchona*;" and the same observation applies to the word "*hyoscyama*;" which would easily be mistaken for "*hyoscyamus*;" and the objection must be still stronger if the alkalies "cinchonina" and "hyoscyamina" should ever be prescribed. The uniform termination in "*ina*," would be very distinctive.—*Dr. Elliotson, in the "Medico-Chirurgical Transactions," Volume 12, Pages 546 and 547.*

<sup>a</sup> Among the energetic substances which the industry and sagacity of continental chemists have extracted from various articles of the *Materia Medica*, and upon which the peculiar properties of these articles appear to depend, none (I believe) have hitherto [1823] been turned to any medical purpose in their separate state, except hydrocyanic acid, iodine, morphina, emetina, and some of those which are furnished by cinchona. An account of the properties of strychnia, veratrina, hyoscyamina, and other alkaline substances procured from vegetable narcotics, is to be found, not in works upon the practice of medicine, but in Orfila's treatise on poisons, or in similar writings of experimental physiologists. Hydrocyanic acid has been investigated (as a medicine) both here and abroad, and deserves a place in our *Pharmacopœia*; although destitute of the high pretensions which were at first injudiciously proclaimed. Of the powers of iodine in bronchocele, we have abundant testimony; I have seen sufficient to satisfy myself; and they would seem equally great in certain other structural diseases. Very little has been written upon the medical virtues of morphina; but it is much employed, in combination with acetic acid, by some eminent physicians, instead of opium; and both it and emetina, as well as hydrocyanic acid, have a place in the "*Codex Medicamentarius*" of Paris. The curative powers of quinina have been highly extolled in French publications; but I am not aware that any thing has yet [1823] appeared in this country upon the subject; and it is for the purpose of beginning to supply this deficiency, that I do myself the honour of offering the present communication to the [Medical and Chirurgical] Society.

Of the three substances discovered in cinchona,—the alcali "quinina" (found in "*cinchona cordifolia*," and more abundantly in the "*oblongifolia*"), the alcali "cinchonina" (found in "*cinchona lancifolia*," and also more abundantly in the "*oblongifolia*"), and kinic acid (found in combination with lime in all three species, and also with quinina in the "*cordifolia*," with cinchonina in the "*lancifolia*," and with both quinina and cinchonina in the "*oblongifolia*"),—the two alkalies only, if I mistake not, have been tried as remedies; and of them the cinchonina appears to have been but once exhibited. Dr. Chomel once prescribed the sulphate of cinchonina in intermittent fever. Six grains mitigated the paroxysms; twenty put a stop to them.

The quinina, in the state of sulphate, is very extensively employed in France; and many relations of its efficacy have been published, in the journals of that country.

In the common run of cases in which we prescribe cinchona, its efficacy is not particularly striking; as we generally employ at the same time nutritious food, perhaps wine and porter, and every thing calculated to strengthen. My general experience of simple quinina as a tonic, is the same as of the sulphate; but I have never observed derangement of the stomach induced by doses of the impure preparation I employed, so large as ten grains, given every six hours. I beg not to be misunderstood as recommending simple quinina, in preference to the sulphate. My object is merely to illustrate the virtues of the substance, whether simple or combined. I may here state, that although none of my friends have yet employed simple quinina, several have prescribed the sulphate; and all with the most satisfactory results. Every case of intermittent fever has presently yielded to it, and in some the bark had previously failed.

It has been apprehended, that the alkalies of cinchona may be analogous to those of narcotics; and their exhibition, consequently, not altogether free from danger. But the fear is groundless. I have used many ounces of both quinina and its sulphate; have frequently given them every day for some weeks; and, even when the quantity of the sulphate or of the impure quinina was a scruple in the twenty-four hours, have never observed the slightest

*Mode of Administering Quinina.*—Quinina is best given in a fluid state; and there should be a slight addition of sulphuric acid; by means of which a super-sulphate is made. Sulphate of quinina is not very soluble; but, by adding one drop of sulphuric acid to every grain of sulphate of quinina, we have a super-sulphate, which is sufficiently soluble. It goes farther, I should imagine, when given in this form; but, on account of its taste, and for the comfort of the patient, we often give it in a solid form. If it be exhibited in a pill, its bitterness is not tasted.

unpleasant effect. Yet there can be no question, that an excessive quantity of so intense a tonic and bitter may disturb. Accordingly, ten grains of the sulphate (at a dose) occasioned vomiting, in the three only instances in which I carried the medicine to that extent. An instance has been related to me of a gentleman experiencing nausea and headache from a dose of ten grains, taken without advice; and another in which five grains, repeated every three hours for six times, caused a degree of uneasiness; and Dr. Magendie says, that when practitioners have gone considerably beyond ten grains, in the twenty-four hours, the patient has sometimes experienced a high degree of excitement, and of cerebral disturbance. But quantities that can disagree, are not required. Five grains of the sulphate, every six hours, is the largest dose that can be necessary; and many cases of intermittent fever have been cured with three, two, and even one grain, every six hours.

I would always continue the medicine, whether using the sulphate or simple quinina, for about a week after the ague has ceased; because I have heard of relapses, where it had been omitted immediately that the disease gave way.

It is very true that quinina and cinchonina cannot strictly be called "*new medicines*," because they exist (one or both) in cinchona, which we have all been prescribing. We are in the situation of M. Jourdain, in Molière's "*Bourgeois Gentilhomme*" (Act 2, Scene 6), who had been speaking prose all his life without knowing it; and we might address the chemists, to whose labours we are so deeply indebted, in language similar to that of the worthy man, on receiving the information from his Maitre de Philosophie.—"Par ma foi, il y a plus de quarante ans que je dis la prose, sans que j'en susse rien; et je vous suis le plus obligé du monde, de m'avoir appris cela." ("By my faith, I have been speaking prose for more than forty years, without being aware of it; and I am under the greatest possible obligations to you, for having taught me the fact.")

The powder of bark requires, generally, to be "thrown in" (according to the apt expression of old practitioners) in pretty large quantities, before the disease is removed; and not unfrequently it fails. But, with respect to quinina and its sulphate, a small quantity is sufficient. The patient has only to take a pill; and is spared the annoyance of swallowing any of the mass of inert powder, which remains after the extraction of quinina; and which frequently (whatever may be the disease) so disgusts him, or so oppresses his stomach, and deranges his system at large, that bark cannot be borne in efficient quantity, or even borne at all; and (what is particularly interesting) we find, that they succeed when bark has failed;—that they cure cases of intermittent fever which have resisted bark, although perfectly well borne, and freely administered.—*Dr. Elliotson, in the "Medico-Chirurgical Transactions;" Volume 12; Pages 543 to 564.*

Since the appearance [in the "*Medico-Chirurgical Transactions*"] of the paper upon quinina, [of which paper the preceding part of this note is the substance,] I have attended nearly a hundred and fifty cases of ague, and have treated them all with the sulphate. Many were combined with so much inflammation (in the abdomen, chest, or head), as to require venesection;—some being combined with dropsy; and some with a chronic disease of the lungs or liver; but all were cured. Having never seen it augment any inflammation that may be present, or interfere with antiphlogistic measures, I have always given it in all circumstances; and have simultaneously adopted any other measures, that might be demanded by other symptoms. Some cases, and those were generally quartans, would not yield to less than five grains every four hours; but this quantity has never failed, after having been exhibited a week or ten days. Like mercury in syphilis, I have frequently seen its use followed by a relapse, when not continued for a proper length of time after the disease. It cannot be a matter of surprise, that a fresh exposure to the causes of ague, will renew it after a cure;—precisely as happens with syphilis, after the successful exhibition of mercury. In London, the disease may in general be arrested *immediately*, by the exhibition of ten grains at once, just before or after the paroxysm.

Dr. Horne found the bark much more successful *after* than *before* the paroxysm; and this is my experience with quinina. I am convinced, that the best practice is first to give ten grains as soon as the paroxysm is over. This almost always (the exceptions are generally quartans) prevents the paroxysm next expected; and, if repeated daily at the same hour, often cures the disease. But as ten grains, given in any number of doses in the twenty-four hours, are frequently insufficient to conquer it, and half a drachm may be required, it is sometimes necessary, in addition to these ten grains after the fit, to make the whole quantity in the twenty-four hours amount to a scruple or half a drachm;—by small doses also, every six or eight hours.—*Dr. Elliotson, in the "Medico-Chirurgical Transactions;" Volume 13; Pages 464 to 466.*

*Dose of Quinina.*—A few grains, every eight hours, will generally cure the complaint. Some give a grain or two, every two hours; and say it answers very well; but others give a larger quantity, at more distant intervals. Either way is very good; but if the stomach reject it, certainly it would be better to give only a grain or two every two hours throughout the twenty-four, rather than a large quantity at once. I have found it the most efficacious mode, to give a large dose immediately after the paroxysm. It is very good to give it *before* the paroxysm; but I think, of the two, more effect is produced by giving it as soon as the paroxysm is over. For the most part, we put a stop to it directly, by giving ten or twelve grains as soon as the paroxysm is over; but we do not usually *cure* the disease;—we only *suspend* it. To effect a cure, we must generally give a larger quantity in the course of the twenty-four hours; and for some time. When we first had sulphate of quinina, I was generally able to cure the disease with two or three grains, two or three times a-day; but that does not generally happen to me now; and therefore I cannot but believe, that this medicine is exceedingly adulterated. I continually have to give people twenty or thirty grains, in the twenty-four hours, before I can cure the complaint.

*Large Doses sometimes Necessary.*—No general rule can be laid down respecting the quantity required. Some persons may be cured by a few grains; and some will require a very large quantity. In February, 1829, I had a patient labouring under quartan ague, which did not yield to less than forty-five grains, in the twenty-four hours. I thought that a very considerable quantity; but in the ensuing October, on my return from the Continent, I found a patient in my wards who, by direction of Dr. Roots, was taking a scruple every eight hours, together with ten minims of Liquor Potassæ Arsenitis. This man, like the former, had a quartan ague; and was no better, notwithstanding he took this large quantity. However, as it did not disagree with him, and as I never failed in curing the complaint, I determined that if it *could* be cured it *should*; and I gave the remedy (as Dr. Roots would no doubt have done, had he continued to treat the case) every *six* hours, instead of *eight*; and he was then cured directly. That was the largest quantity that I have ever been obliged to give; but it was indispensable in this case.

*Time for administering Quinina.*—I should certainly advise a large dose to be given (such as twelve or fifteen grains, in some cases; but eight or ten, in general) immediately after the fit, to *suspend* the disease at once; and then to give a small quantity repeated at intervals during the twenty-four hours, for the purpose of *curing* the disease. In the first case we knock it down at once, which is a material point; because every paroxysm shatters the patient, and is a period of great suffering; and therefore I would stop it immediately. But we shall not always stop it *permanently*, unless we give a larger quantity in the twenty-four hours; and continue it for some time. I am in the habit of giving ten grains, as a medium dose, immediately after the paroxysm; and then five grains every six or eight hours, whether the disease comes back or not.

*Its Employment must not Cease too Soon.*—It is necessary to continue the medicine for some time, after the disease appears to be cured; for if it be left off directly, the disease, in all probability, will return. It is just the same in the cure of syphilis; if we leave off mercury as soon as the sore is healed, or the pain has ceased, the symptoms will possibly return. Although ague, therefore, appears to be quite arrested, it is necessary to continue the remedy for two or three weeks afterwards, in order to make sure of the cure.

*Administration of Quinina during the Paroxysm.*—The remedy may be given with perfect safety even during the paroxysm, when the pyrexia is present, and even though there may be local inflammation; but I should conceive that it is a waste of a good thing, to give it during the paroxysm. At that period the system is in such an unnatural state, that all agents are resisted; and a dose of quinina, that produces a good effect during the intermission, will produce no effect during the paroxysm. Medicines are all resisted, more or less, when we are in an unnatural state. It is found to be more efficacious during the intermission; and sufficient may

then be given to cure the disease. I do not know that it is *injurious* to give it during the paroxysm; but it is certainly *wasteful*.

*When attended by Local Inflammation.*—I have frequently had occasion to give it, notwithstanding there was local inflammation. My object was to cure both diseases; and while I was curing the local affection by bleeding and other means, I stopped the ague with quina; and never saw any harm done by it. When I first employed this remedy, many years ago, I had a patient with ague, who shivered every other day; and had then intense heat and sweating; but during the intermission he was always hot, always had a very quick pulse, and was always thirsty. He had continued fever, with the addition of a tertian ague; or he would have been said by some to have remittent fever. I did not then know a great deal about the remedy; but I gave it him at regular hours, day and night; and he became perfectly cured. Notwithstanding the great feverishness, no inconvenience arose. The case is published in the twelfth volume of the "*Medico-Chirurgical Transactions*;"<sup>a</sup> along with several others of which I made a report to the profession, before the remedy was much known in this country.<sup>b</sup> I have continually seen quina cure the disease,

\* A poor man, named Charles Hunt, was conveyed to me on the morning of Monday, September the first [1823]; and with difficulty was supported into the house. He said that he had laboured under ague at Cowes, in the Isle of Wight, twenty years ago; but was attacked, a fortnight since, with violent vomiting and pyrexia; for which, at the suggestion of some friend, he drank large quantities of cold water;—that in a few days, a severe tertian commenced, without any alteration of the other symptoms; and that he had experienced four paroxysms, every successive one invading an hour earlier, and each of the three stages lasting nearly three hours. I found him excessively hot and thirsty; vomiting every thing he swallowed; with a feeble, rapid pulse; and so weak as to have fallen three times that morning, in walking through a yard belonging to his house. Five grains of the sulphate every six hours, in the form of pill, were ordered. The medicine was not procured that day; and, in the evening, he had a paroxysm an hour earlier than the preceding, and more violent than any. The next day (Tuesday), he began its use; and on Wednesday, to his great delight, he experienced no paroxysm, but merely a chilliness for about ten minutes, followed by neither heat nor sweating. On Friday, I found him much stronger, much cooler, with little thirst, with his pulse greatly reduced, and able to retain every sort of food;—not having vomited since the first dose of the remedy. I write this on Monday, September the eighth; and he tells me, to-day, that he has had not the slightest paroxysm, and that he feels perfectly well. Indeed, he walked to my house,—a distance of three miles; and purposed walking home again. This case is particularly striking, not merely as an illustration of the cure of the disease, but from the circumstance of the violent vomiting and pyrexia—which were constantly present, and would have deterred any one from exhibiting bark in the first instance—yielding completely to the remedy.—*Dr. Elliotson, in the "Medico-Chirurgical Transactions," Volume 12; Pages 560 and 561.*

<sup>b</sup> As soon as the two alkalies of cinchona were discovered, M. Pelletier sent a quantity to Dr. Magendie; who administered them to dogs in large doses, without nausea, vomiting, or other apparent result. The indefatigable and acute physiologist then injected into the veins of these animals from two to ten grains of the sulphate and of the acetate of quina and cinchonina, in solution; but with no more effect. Satisfied of the innocence of the substances, he ordered the sulphate of quina to several scrofulous children affected with ulcers; and, in a fortnight, the most decided benefit was obtained. He mentions, in particular, one child, four years of age, who had scarcely been able to move for ten months, was constantly crying, and ate nothing; but, at the end of six weeks, after taking two grains of the sulphate daily, it acquired a good appetite, became cheerful, walked well, and would not readily have been recognised. In the same paper he states, that a phthisical patient derived considerable benefit from the medicine.

M. Pelletier furnished Dr. Chomel, also of La Charité, with a large quantity of the sulphates; and the following was the result of the exhibition of the sulphate of quina, in thirteen cases of intermittent fever. Ten were cured;—five by the first doses, five by the second; in two the paroxysms were merely mitigated; and in one no sensible effect was produced. In the three unsuccessful cases, the cinchona itself equally failed. The medicine was taken, dissolved in water, on an empty stomach, before the accession of the paroxysm; and the whole quantity was generally six or eight grains, but twice this amount when necessary.

In September and October, 1820, M. Double tried the sulphate of quina in six cases of intermittent fever. In the first, the disease never returned after the exhibition of three grains three times in the interval; smaller doses were subsequently continued for some time. In the second, which occurred in a child, one grain night and morning retarded and deranged the course of the first paroxysm, and a second never took place. The medicine was given for some days, in gradually diminished doses; and the patient recovered her strength, and

when bark was given in as large a quantity as could be borne; and likewise arsenic; and both had failed. I have also known it stop vomiting. When a person with ague has been exceedingly troubled with vomiting,—with great irritability of sto-

a healthy state of her digestive organs. The third case occurred in a young female; and was cured with two grains night and morning. The fever, which was quotidian, instantly lost its intensity, and ceased after the third day; and the patient's health improved in a way that could not have been expected. The fourth was a tertian; four grains were taken twice in the interval; the next paroxysm was of the slightest description, and no other was experienced; the medicine was continued some time. The fifth and sixth cases were equally decisive. M. Double prescribed it in a variety of diseases, which are usually treated with cinchona; and for the most part, he says, with satisfactory results.

Instances of the equally successful exhibition of the sulphate of quina, by MM. Villermé, Magendie, Talbot, and Dupré, are also recorded.

M. Piedagnel has published a case of violent periodic pain of the supra-orbital nerve, entirely cured by the administration of ten grains of the sulphate, during one of the daily intermissions, and a repetition of the same doses in the following twelve hours; with the view of greater security. M. Dupré relates a case of violent periodic pain of the infra-orbital nerve, that subsided after the exhibition of twenty-four grains, in small doses, during two intermissions; and one of remittent sciatica, which yielded very speedily. Two instances of periodic pain of the facial nerve, treated (with equal success) by M. Ribes, will be found in the same pages. M. Dupré likewise gives us a case of typhus, in which a rapid movement took place, after the use of the sulphate of quina was commenced.

I ordered it, largely and perseveringly, in one case of irregularly intermittent, and in one of remittent, pain of the face; but without advantage. Like M. Dupré, I employed it in a case of typhus; and with eminent advantage. On the nineteenth of June [1823], a poor Irish-woman, half starved and flooding, was brought into St. Thomas's Hospital, labouring under severe typhus. She was supported by plenty of beef-tea and milk; the epigastrium, forehead, and occiput were blistered; and Hydrargyrum cum Creta was prescribed, in doses of one scruple, and sometimes two scruples every six hours, till the mouth grew sore. The delirium and stupor were entirely subdued, and the tongue became clear and moist; but the debility increased hourly. The face became ghastly, and the body sunk lower in the bed. I ordered three, and soon five grains of sulphate of quina, to be given every six hours; and the diet to remain as before. A striking amendment was observed the next day; and she speedily recovered. After being convalescent some time, the medicine was omitted; but, when I thought of discharging her, she suddenly relapsed into extreme prostration of strength, passed her urine and fæces again involuntarily, and grew delirious; but the tongue remained clean and moist. The two blisters to the head were repeated, and the sulphate ordered as before;—milk and beef-tea, *ad libitum*, continuing to be her diet. The amendment was not so sudden; but, from the first day of recurring to the medicine, the debility ceased to increase. In a few days, she clearly gained strength; and was soon convalescent. After taking the full diet of the house, and a pint of porter daily, for two or three weeks, she was discharged,—perfectly strong and well.

The three following are all the cases of intermittent fever in which I have yet [July 8, 1823] prescribed it; and they corroborate the assertions of the French. They, as well as the rest which I shall detail, occurred in St. Thomas's Hospital. The medicine was given in the form of pills. 1. Elizabeth Taylor came under my care, as an out-patient, on the nineteenth of September last [1822]. She had laboured under intermittent fever for nearly a twelvemonth, in Gloucestershire, when thirteen years of age; and had experienced a solitary paroxysm occasionally; and once so severe a return, as to confine her two months in St. Thomas's Hospital. The disease had now regularly recurred, in the quartan type, for six months. I prescribed five grains of the sulphate of quina every six hours. On the tenth day (September 28) I saw her again; and learnt that a paroxysm took place on the first regular day, (namely, the twenty-first of the month,) but without any cold stage; that the hot stage was very mild; and that the disease had not subsequently returned. The same prescription was continued. On the eighteenth day (October 6) she informed me, that there still had been no return; and I continued the prescription. She never applied again;—remaining, no doubt, perfectly well.

2. The second case was that of an Irishman, named Hugh Kaney; who was admitted into the hospital on the twenty-seventh of March. He laboured under tertian for five days. I prescribed five grains of the sulphate of quina every six hours. A paroxysm took place on the day after his admission; but, although he remained in the hospital until the eighth of May, he never experienced another. The medicine was continued, in the same quantity, till the twenty-second of April.

3. The third case proved more refractory; but the disease was instantly influenced by the medicine, and removed in little more than a fortnight. Robert Tindall was admitted into the hospital on the twenty-seventh of March; having laboured under tertian for a month. I prescribed five grains of the sulphate of quina every six hours. On the sixth day (April 1), I found that the paroxysms had returned regularly, but less severely, and at a later hour; on the tenth (April 5), that they were still milder, and on the thirteenth (April 8), that they

mach, I have known it put a stop to the irritability as well as to the ague. Still it is to be remembered, that now and then it disagrees with the stomach. Now and

had become much milder. On the fifteenth (April 10), the paroxysm was severer than it had lately been; but on the nineteenth (April 14), it returned very mildly, and for the last time. The same quantity of medicine was continued till the twenty-sixth day (April 22); and he left the hospital on the forty-ninth (May 15), without the least return of the disorder. I have reason to believe, that the medicine which this man took was of inferior quality.

1. I first prescribed the quina itself, on the 29th of November [1822], for a woman named Martha Pallow, who had been affected with quotidian for a fortnight; the paroxysms always commencing at four o'clock in the morning. Five grains every six hours were ordered. She visited me again on the seventh of December (the next day for seeing out-patients); and said she had experienced no paroxysm since the seventh day (December 4). The medicine was continued in the same doses; but she never applied again: and probably, therefore, remained in good health.

2. William Johnson was admitted into the hospital January 23 [1823];—having laboured under tertian for ten weeks. He was ordered the same doses, at the same intervals. A paroxysm occurred on the day of his admission, but more mildly than before; and he had no other up to the eighth day (January 27); when he left the house of his own accord.

3. Edward Cupon had tertian in Norfolk, twelve years ago; was now a surgical patient in the hospital, and desired my assistance on the fourth of February [1823], on account of a quotidian, which had existed three weeks.—The same prescription.—On the fifth day (February 8) I found that he had experienced no paroxysm, but merely a coldness of the loins, legs, and feet, at the customary time of the paroxysm. On the eighth day (February 11) he said, that even the coldness had ceased to take place; and, up to the first of May, he remained free from the disease.

4. Francis Douglas had been afflicted with intermittent fever, irregularly, for eighteen months;—at first daily for six weeks, in the West Indies. Since that time he had made a voyage to China; and for five months had no paroxysm. One attacked him on the second of February last [1823], in the morning, one on the sixth in the evening; and one on the eighth, (the day on which I first prescribed for him,) at noon. He complained of a degree of shivering every day. The same prescription was written for him. He had no paroxysm from the day he commenced the use of the medicine, till the eighth (February 15); and then none till the fourteenth (February 21). No other occurred during his residence in the hospital.

5. Daniel Duff was admitted on the thirteenth of February;—having laboured under quotidian a fortnight.—The same prescription.—A paroxysm took place on the two first days after his admission; but they were slight, and the second was slighter than the first. Up to the twenty-seventh of the month he had no return, and was then discharged.

6. Edward Perry, ill a twelvemonth with tertian, was admitted February 13 [1823]. He had laboured under the disease in Wiltshire, thirty-six years ago; but never since that period till the present time.—The same prescription.—The paroxysms at once became slighter, and recurred but twice after the use of the medicine.

7. John Ferguson, affected with tertian for three weeks, was admitted on the eighth of March.—The same prescription.—No paroxysm took place after the use of the medicine was begun.

8. An old woman, of the name of Traylen, had laboured under quartan for ten weeks. She had been subject to it for many years; but always previously stopped the paroxysms, by a smaller quantity of cinchona than failed the last spring [1823]. The same doses of quina were followed by an immediate cessation of the disease; and, though three months have elapsed, it has not recurred.

9. Daniel Carthy was admitted on the twenty-ninth of May [1823], on account of tertian. He had the same prescription as the rest. The only paroxysm that took place, was the day after his admission; and he was discharged at his own desire, at the end of three weeks.

10. Bryan Summers was admitted on the same day as Carthy, on account of a tertian, caught at Tilbury Fort. The same prescription was given to him. A paroxysm occurred immediately after his admission; but it was not succeeded by another. A chilliness of the legs came on every other day, for some little time; but this gradually decreased, and he was discharged at the end of three weeks.

The following case, furnished me by my friend and colleague, Dr. Roots, is exceedingly worthy of detail;—as affording an instance of the immediate success of the sulphate, after the failure of both bark and arsenic:—"Mrs. Sullivan was admitted into St. Pancras Infirmary on the seventh of May [1823]; after having suffered under tertian for nearly a month. She took the *Liquor Arsenicalis* [*Liquor Arsenitis Potassæ*] from the eighth of May to the twenty-third; and every two or three days rhubarb and calomel, without any advantage. From the twenty-third of May to the sixth of June, she took cinchona in drachm doses, every six hours, with the decoction and tincture;—containing, at times, the rhubarb and calomel. As the paroxysms still returned at the regular period, the cinchona was discontinued, and the *Liquor Arsenicalis* resumed, in doses of nine minims every six hours; which she took from the sixth of June to the twentieth. On the thirtieth, finding the paroxysms still return at the usual period, I ordered her five grains of the sulphate of quina, in a pill, every six

then it produces vomiting and gastrodynia;<sup>a</sup>—just as bark will do; and, more frequently still, it will also purge. When the stomach is disordered by it,—whether it be thrown into spasmodic pain, or vomiting be occasioned,—we may give aromatics, or opium, or (which is far the best) prussic acid. If there be mere pain, an effervescing draught will not be of any use; though it might be servicable if there were nausea and vomiting.

*Failure of Quinina from Gastric Irritation.*—The power of quinina is one of the most extraordinary facts in medicine; and always reminds me of the lines in Virgil,—

“Hæc certamina tanta  
Pulveris exigui jactu compressa quiescent.”<sup>b</sup>

It is said to have failed sometimes; and that bark has then cured the affection;—just as, in many cases, I have seen it *successful*, when bark had *failed*. When this has happened, it has been (I imagine) from its disagreeing with the stomach; so that a sufficient quantity could not be taken. Cases have occurred to me, in which the stomach became so irritated, from the intensity of the medicine, that the patient rejected it; and could not take it in sufficient quantity; whereas bark, being far less intense, could be borne; and was taken in such a quantity as cured the disease. I had a case exactly of this description, in the lady who caught an ague from walking on the ramparts of the Tower.<sup>c</sup> A very small dose of sulphate of quinina produced most excruciating pain at the stomach; and she could not persevere with the medicine. Bark was substituted for it; was borne very well; and cured the disease. Whether, if she had taken tincture of opium, or prussic acid (in proper quantity) the quinina could then have been borne, I do not know; but I think it probable that it might; and that it would then have cured her. I think Andral mentions the circumstance of quinina having failed, and of bark subsequently curing the disease. I do not know the particulars of his cases; but I imagine that such a circumstance as this, could only arise from the medicine irritating the stomach,—so that it was not taken in a sufficiently large quantity; because it has all the virtue of the bark, and in far greater intensity.

*Other Barks in Ague.*—Many other barks, however, cure the disease. The bark of willow, the alcaloid principle of the willow-bark (salicina<sup>d</sup>), swietenia,<sup>e</sup> all astringents of the vegetable kingdom, and more especially a combination of both (such as calumba<sup>f</sup> with galls) will cure the affection. A combination of these, is found to be more powerful than either of them taken separately; and those barks which contain both a natural bitter and an astringent, are those which answer best. It is said, with respect to these, that they have sometimes cured the disease, after Peruvian bark has failed; and various other combinations of bitters and astringents, have done the same. Piperine will cure ague.

*Arsenite of Potassa.*—Next to sulphate of quinina or bark, however, certainly comes arsenic. The solution of arsenite of potassa, is what is commonly used; in doses of from two to ten, or twelve drops, or more, two or three times a day. It is best to give this remedy in a very gradual mode: and I never begin with more than two or three drops, three times a day; gradually increasing it. I have seen

hours. She took twelve doses;—never having any return of the paroxysm after the first dose; and was discharged on the second of July.” It is right to mention that, the day prior to the sulphate of quinina being ordered, she was allowed a pint of porter daily. Dr. Roots, I may add, has hitherto [July 8, 1823] employed the medicine but once since; and says, in his letter to me,—“In another case of quartan, the sulphate was given in doses of two grains every six hours; and was equally successful.”—Dr. Elliotson, in the “*Medico-Chirurgical Transactions*,” Volume 12; Pages 546 to 561.

<sup>a</sup> From *yarrne*, the stomach; and *odun*, pain.

<sup>b</sup> “On a light powder being thrown, the contests (though violent) cease.”—“*Georgics*,” Book 4; Lines 86 and 87.

The allusion is to the effect of a little dust, thrown on bees engaged in battle.

<sup>c</sup> See Page 251.

<sup>e</sup> So named from *Van Swieten*.

<sup>f</sup> So named from *Colomba*, in Ceylon, whence it is obtained.

ague cease from the first day it was given, although the disease had continued for a length of time; but frequently a longer period is required, for its successful exhibition. The largest dose required, I believe, is from twelve to fifteen drops, three times a day; or as frequently as is necessary. I never had occasion to go beyond that; nor should I like to do so. I need not say that, on account of its virtues in this disease, it has been made a nostrum of;—exactly as was the case with bark. What is called “Tasteless Agne-Drop,” is a preparation of arsenic.

*Mode of Administering Arsenic.*—It is always best not to give this medicine on an empty stomach. When giving an acrid matter,—such as iodine, the bichloride of mercury, or antimony,—with a view, not to nauseate, but merely to produce diaphoresis, it is by far the best practice to exhibit it after food has been taken. It is evident that any thing acrid, coming into direct contact with the mucous membrane of the stomach, is more likely to irritate it, than if food had been first taken;—so as to cause it to be applied to the stomach partially and gradually. Whenever Peruvian bark or sulphate of quina irritates the stomach, it is best to try whether it will not be borne when given after meals. But in the case of arsenic, we should make it a rule never to give it before breakfast. Persons are continually nauseated, and will even vomit if they take it before breakfast; whereas *after* breakfast they may bear it very well. When it produces nausea or vomiting, a little tincture of opium is indispensable; indeed it is well, in general, to combine a little tincture of opium with every dose of arsenic.

*Ill Effects of Arsenic.*—The ill effects of arsenic are symptoms of gastritis. The slightest symptom is nausea; the next is vomiting; then pain of the stomach, and heat there; tenderness on pressure; and heat extending up the throat. Arsenic has a tendency to excite gastritis, even when not taken into the stomach. I knew an instance of a person being seized with gastritis, and thrown into the greatest danger, simply from having arsenic applied to a sore of the leg. One of the first effects of arsenic, is to irritate the stomach; and the irritation soon arises to the pitch of inflammation; but it will also produce other effects. Singularly enough, it occasions soreness and redness of the tarsi; redness and heat of the fingers; soreness of the throat; and œdema of some part of the body. Very frequently, when patients have been taking arsenic, I have seen the face swell; and sometimes the lower extremities. Sometimes it is one part, and sometimes another; but most frequently it is the face. Frequently, too, there is heat of the system. When this local inflammation of the stomach, throat, or face, takes place, the whole body will become more or less excited;—so that we have general pyrexia. In this case, it is necessary to omit the medicine immediately;—not to lower the dose, but to omit the medicine altogether; and the symptoms generally decline; though it may be necessary to apply leeches freely at the pit of the stomach, or to bleed. I never, but once, saw any harm ensue; and in that case the remedy had been carried on very injudiciously. If, while giving arsenic, we look carefully at the patient's face, and ask about his throat, and also respecting the state of the stomach,—as to whether there is pain, tenderness, nausea, heat, or vomiting,—I believe no harm can arise.

*Arsenious Acid.*—It is asserted, but I cannot say from experience whether it is correct, that when *Liquor Potassæ Arsenitis* has failed, pure arsenic has succeeded;—that is to say, what is called “arsenic” in commerce, has succeeded; when its combination with potassa, according to the directions in the *Pharmacopœia*,<sup>a</sup> has failed. It is said that about the sixteenth of a grain may be given, three or four times a day; that the eighth of a grain can seldom be borne; but that the sixteenth

<sup>a</sup> The mention of the *Pharmacopœia*, gives us an opportunity of recommending to the attention of our readers—“Diagrams, explanatory of the Chemical Decompositions of the London *Pharmacopœia*, and of the various Processes used in Medical Chemistry; by Thomas Harper Whitaker.” The plan adopted in these Diagrams, is that invented by Dr. David Boswell Reid (see his “*Elements of Practical Chemistry*”); and is far superior to any other in perspicuity. We may also mention a kindred work, the title of which is of too unprofessional a character to accord with our taste:—“*Sparks from the Wheel of a Man wot Grinds. A Light on the Pharmacopœia.*” Both these works are published by Butler, Medical Bookseller, St. Thomas's Street, Southwark.

of a grain succeeds very well. This is stated by Dr. Macculloch, in his first volume on "Marsh Fever;"<sup>a</sup> but I never exhibited it. Many other minerals, which are astringents, will cure cases of this disease;—sulphate of zinc, oxide of zinc, sulphate of copper, and alum. Muriate of ammonia is likewise said to have a power over the disease; and it is thought by many, at least abroad, that it heightens the power of bark. Carbonate of potash is supposed to possess some virtue. A combination of some of these things is thought to be best: but no doubt sulphate of zinc, and sulphate of copper, will frequently cure the disease.

*Opium, Sudorifics, and Emetics.*—As a full dose of sulphate of quina, or a full dose of bark, is found more useful immediately before the paroxysm, than at other periods of intermission (except immediately after it is over), so various other remedies have been employed at this period. These have been of various kinds;—sometimes medicinal; and sometimes calculated only to make an impression on the mind. Immediately before the beginning of a paroxysm, a large dose of opium has sometimes prevented it from coming on violently. Sudorifics and emetics have been employed for the same purpose. Mental emotion has been excited at the moment with a similar view; so that a child has been flogged out of his ague, or frightened out of it by threats. He has been threatened with a good thrashing, if his ague came on; and there can be no doubt that this has cured his complaint. Sometimes by exciting disgust,—by insisting that a person should swallow spiders and cobwebs, the paroxysm has been prevented. Some persons, however, imagine that the latter really possess a power in preventing the disease. I have no personal knowledge of the virtue of spiders and cobwebs; but Dr. Chapman's work on *Materia Medica*,<sup>b</sup> contains a very strong testimony in favour of the soothing effects of cobweb. He mentions that it will procure sleep in fever, and tranquillize the system, when all other things have failed. I know that many persons declare that it has a sort of sedative quality; and there is no reason why it should not; but, in the cure of ague, it has been employed merely with a view of exciting disgust; and has succeeded. These effects might be produced at any time during the intermission; but it is immediately before the paroxysm that disgust, or fright, or violent emotion of mind, is most likely to be of use.

*Great Value of Bark and Quina.*—The great remedies for the disease, however, are quina and arsenic,—all other means being more or less uncertain, except perhaps salicine. I never think now of employing any thing but quina; though, in particular circumstances, I might be induced to order venesection. These two medicines (quina and arsenic) are equally good in other complaints of an intermittent, though not aguish, character. In intermittent rheumatism and neuralgia, they are among the best remedies. It is a singular circumstance; but, even in intermittent vomiting, arsenic has been known to effect a cure. In the volume of the "Transactions of the London Medical Society" for 1817,<sup>c</sup> there is a paper by Dr. Adams, on periodical vomiting, coming on at certain intervals; which was cured by what would, in many cases, have produced vomiting;—a small quantity of arsenic.

<sup>a</sup> In as far as it does fail, there is reason to think that the fault is very often in the remedy itself; and I cannot concede that the well-known combination of this substance (or, rather of its primary acid), with potash,—commonly called "Fowler's Solution,"—is the proper mode of using it. It is certain, at least, that when this has failed, the same substance (or the common arsenic of the shops) in powder, has often succeeded, and even immediately. Of this the sixteenth part of a grain is equivalent to the common dose of the solution, and is capable of being repeated three or four times in the day; while it is conveniently divided by means of white sugar, which also aids in reducing it to that fineness of powder, which cannot be too perfect. With respect to the superiority of arsenic in substance to its neutral salt, [arsenite of potash,] I may quote the experience of a friend, who—residing in a district where "tic douloureux" is extremely common, and where the solution seldom succeeded—now reports to me; that he finds the powder almost infallible;—giving it without the least inconvenience to the extent of one-twelfth of a grain for a dose, and finding that its utmost limit is one-eighth; which, however, can seldom be endured; though he has administered one-sixth, without further evil consequences than griping.—"*Essay on Remittent and Intermittent Diseases; including (generically) Marsh-Fever and Neuralgia.* By John Macculloch, M. D." Volume I; Pages 452 and 453.

<sup>b</sup> See Note to Page 273.

<sup>c</sup> Volume I; Part 2; Page 89.

Whenever complaints assume an intermittent form, whether they be aguish or not, the sulphate of quina, and arsenic, are among the best remedies. If either of these failed separately, I should not hesitate to give them both together. I have failed with arsenic, but not with quina. Whenever a case was obstinate, I increased the dose to the largest quantity the stomach would bear.

*Is it Dangerous to Stop an Ague?*—It was formerly imagined that ague was too good a thing to be cured;—that it was very wrong to stop it. At any rate, many contended that it ought not to be stopped, till the patient had gone through a certain preparation. I have astonished many persons (who, when abroad, were accustomed to see some preparation employed before the remedies for ague were given) by stopping the disease immediately. I never saw any harm done by it; though if there be any local affection of the head, chest, or abdomen, we must take care to attend to that at the same time. If there be any congestion of the head, lungs, or abdomen, it may be necessary to bleed, to purge, and to use all the remedies for such a state as that; for if we do not, it is possible that the circumstance of stopping the ague at once, may be useless. If we do every thing indicated by the local affection, I am quite satisfied there will be no danger in stopping the ague. I never did harm by it in a single case. I never lost a patient from ague; notwithstanding that I gave sulphate of quina when local inflammation was present. Arsenic, I need not say, may be very proper when the inflammation which is present affects the stomach; and in the case of gastritis, possibly neither arsenic nor quina can be borne; and we do not remedy the morbid condition, till we adopt either local or general bleeding.

So far from the stoppage of the ague doing any harm, I have found any local disease that might be present, removed the more easily; for every attack of ague of course disturbs the circulation, renders it more irregular, and is likely to throw a greater load of blood upon those organs which are already in a state of congestion. At any rate, ague always makes bad worse. I have always considered that I have treated local complaints more successfully, by having stopped the ague. Sydenham says—"Cure the ague first, and then you will easily cure the dropsy; which otherwise might be impossible." I never saw any chronic complaints ensue, on stopping ague. I believe they do not arise from the ague; but are, like ague itself, the result of malaria; and I know that, for many of them, one of the best remedies is sulphate of quina, bark, or arsenic. I have seen many cases of dropsy vanish, on the exhibition of sulphate of quina, without any thing being conjoined with it. If we stop the ague, all those effects which are ascribed to it, whether they be acute or chronic, are cured more safely. Still it is possible that ague sometimes may not give way, till we have remedied the local mischief. It is said that, now and then, ague will not yield to any thing, till we make use of local bleeding. Many say they have met with cases, where bark would not cure the disease, till they made the patient's mouth sore. I never met with a case of that description; but still it is so asserted. If what is said be correct, such a practice must be adopted; but I should, nevertheless, in such a case, go on with the quina, while I was giving the mercury, or making use of local means.

*Prevention of Ague.*—With regard to the *prevention* of ague, the great point is to drain the country, and to prevent all accumulations of dead vegetable substance;—in order to prevent, as much as possible, exhalations from putrefied vegetable matter. When land cannot be drained, occasional inundations may be necessary;—in order to throw more water upon it than is compatible with vegetable decomposition. With regard to individuals who must be exposed to ague, the best mode of preventing it is to live as well as possible; to have good food; a certain portion of wine or beer; and never to expose themselves to malaria with empty stomachs. Persons so situated, ought always to take something before they go out of doors; and where malaria is very intense, spirits may be found necessary. Smoking is an excellent preventive, in damp places. I mentioned<sup>a</sup>

<sup>a</sup> See Page 259.

that when Napoleon was in Italy, he found the advantage of keeping up good fires, in preventing disease. When persons are obliged to live in a house where there is malaria around, it is best to sleep as high as possible;—rather to condescend to sleep in a garret, than to aspire at sleeping in the best apartments; and it is of great importance to avoid going out at night, or very early in the morning. It is said that a gauze-veil around the head, when persons must be exposed, is likewise of use. It might be highly beneficial for a person exposed to malaria, to take sulphate of quina.

## CHAPTER V.

### CONTINUED FEVER.

*Definition.*—The same constitutional symptoms which occur in any intense local inflammation, are those which, generally speaking, characterize continued fever. There is quickness of pulse, increased heat, and diminution of the secretions. From the latter circumstance we have thirst, dryness of the skin, scanty and high-coloured urine, and costiveness. There is usually restlessness and watchfulness. At first, as at the beginning of inflammation, and as in intermittent fever, there are the opposite symptoms of chilliness (even amounting to rigors), coldness, paleness, and smallness of the pulse; but these, in general, last only for a time. Andral, according to some observations which he made at Paris, in 1822, on two hundred and twenty-nine cases of fever, says that chilliness rarely occurs on the first two or three days. However, I have been attentive to this circumstance; and I know that people in London, at the very *beginning* of continued fever, do frequently complain—more frequently than not—of chilliness; and of those symptoms which are analogous to the first stage of intermittent fever. If, however, these symptoms do take place,—rigors, chilliness, and smallness of the pulse,—they usually last but for a short time. They soon yield to symptoms of excitement; and these symptoms continue throughout the disease; though perhaps, after a time, they are united with symptoms of great debility;—just as is frequently the case in inflammation.

When those symptoms, which I have now mentioned, occur quickly and acutely, they show the existence of continued fever; more especially if the morbid appearance of the tongue, the heat, the quick pulse, and the thirst, be out of all proportion to any signs of local inflammation that may exist. In these circumstances we consider that the patient has *fever*, in the proper sense of the word;—*idiopathic* fever;—fever as distinguished from mere pyrexia. Local inflammation frequently exists at the same time; but whether local inflammation is *always* present or not, is a theoretical question upon which I will not now enter. These symptoms, however, very frequently occur without any *evidence* of local inflammation; and are as frequently out of proportion to any that we may observe; and it is this circumstance that makes us consider the person as labouring under *fever*, properly so called.

### SECTION I.—SYMPTOMS AND PROGRESS.

The general symptoms of continued fever vary;—from those which characterize an *active* inflammation, down to those which accompany an *atonic* or a *passive* inflammation, or even those which denote mortification;—so that we have symptoms of activity and strength, and all the intermediate shades and degrees, down to symp-

toms of extreme prostration of strength; and even a disposition to putrescency in the fluids of the body.

*Early Symptoms.*—In an attack of fever, there is (from the first) more affection of the head, than when the constitutional symptoms of mere inflammation occur. There is generally (at first) more or less confusion, giddiness, and drowsiness; perhaps even stupor or watchfulness. There is generally, from the first, pain of the loins; with a complete loss of appetite, and a general sense of debility. The countenance, too, in fever, is almost always expressive of heaviness and anxiety. The countenance of continued fever, is exceedingly characteristic; the patient is both very heavy in his look, and is evidently, at the same time, labouring under a degree of uneasiness. Sometimes, in these circumstances, the face is pale; but still there is the heaviness and the anxiety. Sometimes the face is flushed, and the eyes look red; and there is frequently great heat of the head. The vessels feel to the patient to throb; and they feel so likewise to the medical attendant. There is then great pain usually felt in the forehead. The tongue is generally tremulous;—whatever may be its appearance as to dryness or colour. The extreme feeling of weakness, and the aching of the loins, in the beginning of this disease, are no less characteristic than the countenance.

*Heat of the Surface.*—As to the particular symptoms to which I have just now alluded, the heat is sometimes intense. The temperature of the body will sometimes rise to 104°, 108°, or 110°; and sometimes it is of that peculiar character which authors have denominated *mordant*;—a pungent, or biting heat. Galen, Sir John Pringle, and Sir Gilbert Blane, all speak of “mordant heat.” Galen, when treating of autumnal remittent fever, says, that the great mark of it is the mordacity and acrimony of the heat; which erodes the touch, just as smoke does the nose and eyes. (“Maximum indicium est mordacitas et acrimonia caloris; quæ, perinde ac fumus nares et oculos, sic ipsa erodere tactum videtur.”) This peculiarity of heat is not felt, he says, the moment the hand is applied; but is perceived on continuing the hand upon the patient for a certain time. Sir Gilbert says, that in ship-fever, there is a peculiar heat of the skin;—a glow of heat imposed upon the palm of the hand of the practitioner, who has grasped the wrist of the patient; and which lasts some hours, if the hand be not washed sooner. He adds, that he never saw this in the sporadic fevers of England; though he has been informed of its occurrence. Andral also mentions the same circumstance. He says that, in the continued fever of Paris, the heat of the skin was in one case very high, acrid, and mordant;—leaving a sense of heat for some time upon the hand of the practitioner;—a sensation, he says, very nearly allied to pain. (“La chaleur de la peau étoit devenue très élevée, acre, et mordicante. En laissant quelque tems le doigt en contact avec elle, on éprouvoit une sorte de sensation pénible, voisine de la douleur.”) Sometimes, however, the heat is not increased in fever; or if it be increased, it is only partially; and it varies in degree at different times. Occasionally, the temperature in fever is below what it ought to be; and, in the last stage, there is sometimes absolute coldness.

*The Pulse.*—The pulse, like the temperature, is generally increased. The pulse in continued fever may be full or hard, soft, small, or weak. Like the temperature, it may be of all degrees. As the temperature may be from 110°, down to far below the natural standard, so the pulse may be quick, full, hard, and strong; or it may be more or less slow. It may be so feeble, as to be easily extinguished;—to be what is called a “fluttering,” or a “vermicular” pulse. It varies in this way, according to the tonic or atonic character of the disease; and according to the stage of the affection. In examining the pulse, if there be signs of debility, and the pulse be strong, we ought to examine the actual state of the circulation at the heart itself. We ought, if we be in any doubt, to resort to that method; for occasionally there may be the extreme debility of fever, with rather a strong pulse. The heart may be in a state of disease; which, in consequence of not having seen the patient before his present illness, we may not be aware of. The heart may be greatly thickened; and, although it may be acting less forcibly than it did before the attack

of fever, yet it may act (from its thickness) so as to produce a full pulse;—such a pulse as might incline us to adopt active measures.

The quickness of the pulse in fever may amount to about 200. Such a pulse as that cannot be counted at the wrist; but we may count it, with perfect ease, at the heart itself. The usual range of the pulse, however, in continued fever, is from 90 to 160. Occasionally it is not quick;—just as the heat occasionally is not increased; nay, it is sometimes even slower than it should be. This takes place chiefly when the head is very much oppressed. It occurs sporadically from the state of the head, or from some peculiarity in the individual's constitution. It has, however, occurred epidemically. There have occurred epidemical fevers, in which one of the characters was slowness of pulse. De Haen mentions a sporadic case of very severe fever, in which the pulse was only 44. Sarconi, in his account of an epidemic which prevailed at Naples, states that the pulse was hardly more than 40 in a minute, in some cases.

Occasionally in fever the pulse is regular; while in health it is intermittent. Many such instances are upon record. Andral mentions a case of fatal fever, where the pulse at first was intermittent; but as the symptoms grew worse and worse, the pulse became more and more regular; till at last it was perfectly so. Rasori, the celebrated Italian physician, mentions the case of an individual, in whom the pulse was regular till the fever was over; and then it became intermittent. He therefore inferred that his pulse, in health, was naturally intermittent. De Haen also mentions the case of a man, who had an intermittent pulse at all times, except when he was labouring under fever. Monro and Shenkius mention such cases; and Dr. Heberden himself saw two persons, whose pulse was always intermittent, except during illness. Dr. Heberden knew a female, who had intermittent pulse all her life; and who at last died of cancer of the womb; but in whose circulating system an able anatomist could discover nothing unhealthy.

*State of the Skin.*—The skin in fever is usually dry; but, as a favourable change takes place, it becomes more soft; and the moisture is for the most part general. Sometimes, however, in fever there are partial sweats, which are by no means favourable; and when death is near at hand, then the sweats are generally both cold and clammy. Sometimes the sweats are offensive; especially if there be great debility. Upon the skin are not unfrequently seen spots;—discolorations of various sizes. If they be exceedingly small, they are called *petechiæ*; if larger, they are termed *vibices*;\* if still larger, they are denominated *ecchymoses*. These spots are of various shades; from a tolerable bright redness, down to a purple hue. They occur particularly in the last stage of the disease; where there is extreme debility; but sometimes they occur where there is *not* great debility. At particular periods, continued fever is characterized by them; and I once saw a greater number of instances of that description within three months, than I had ever seen before during many years.

*State of the Tongue.*—The tongue is usually dry in fever. With respect to colour, it may be white, or yellow, and loaded; it may be of a whitish brown, or really brown; or it may be absolutely black. Occasionally it is brown down the middle; and has a broad white band on each side;—the edges, perhaps, being red. It is sometimes of a reddish brown. Occasionally it is red, glazed, smooth, and dry; and not unfrequently, in these circumstances, it is cracked also. It is very common to see it more or less white or brown on the back; with redness at the tip, or redness at the edges. Occasionally it is extremely pale. When the tongue is of a reddish brown, or really brown, or absolutely black, we usually have likewise collections of black matter about the teeth and lips;—"sordes,"<sup>b</sup> as they are called. They are the result, no doubt, of vitiated secretion; and sometimes they are partly the result of a little effusion of blood, which coagulates; and, uniting with the secretion, contributes to their formation. The tongue is generally tremulous; and frequently the extremities are in a similar state;—so that, when the patient attempts to move, his

\* From "*vibex, vibicis*," a mark of a blow.

<sup>b</sup> Filth.

hands or his legs tremble; but even when they do not, we may generally observe a tremor of the tongue. From the dryness of the tongue, and perhaps of the fauces, the patient necessarily suffers thirst. The breath is frequently offensive;—much more so than the perspiration.

*The Urine.*—The urine is scanty and high-coloured;—containing an excess of the lithates, and the purpurates (chiefly the purpurate of ammonia, but also the purpurate of soda); together with the yellow colouring matter, which naturally exists in the urine. As the fever declines, the lithates become super-lithates, and are precipitated; so that we have a red sediment. The urine has a strong animal smell; and not unfrequently it has a strong ammoniacal smell; and almost as soon as it is discharged, it rushes into a state of putrefaction. Occasionally the urine is very dark-coloured; and sometimes it is bloody.

*The Stomach.*—With respect to the stomach, the appetite, for the most part, is lost; but—just as there are extraordinary instances, from time to time, with regard to the pulse, (such as its being regular in fever, while it is intermittent in health,)—so, with respect to the appetite, there are upon record cases in which, so far from its being lost in fever, it was much increased. In the fifth volume of the “Transactions of the College of Physicians,”<sup>a</sup> Dr. Satterly mentions the case of a boy who laboured under typhus-fever, attended by marked inflammation of the head. The exacerbations of the fever were always attended by a voracious appetite;—so that, in the midst of the fever, he would eat four meals a day; and each meal would have been sufficient for a stout labourer.<sup>b</sup> Besides these four meals of meat and vegetables, he daily ate many pounds of dry bread, biscuit, and fruit.<sup>c</sup> He had no sooner eaten a meal, than he denied that he had eaten any thing; so that the more he ate the more he desired:—

“Cibus omnis, in illo,  
Causa cibi est; semperque locus fit inanis edendo.”<sup>d</sup>

If he was not fed the moment he requested it, he sucked the bed-clothes and bit his fingers;—in this, also, bringing to one’s mind Ovid’s account of Erisichthon:—

“Ipse suos artus lacera divellere morsu  
Cœpit; et infelix minuenda corpus alebat.”<sup>e</sup>

This boy discharged several very copious stools a day; and he recovered perfectly. The appetite, however, usually returns as the disease declines; and when the disease is first gone, the appetite is for the most part voracious. Persons say there is nothing the matter with them; but that they are hungry. The stomach, however, is frequently much more affected than with mere loss of appetite. Even from the very first there is nausea; and, in many cases, vomiting. Sometimes the vomiting does not occur from the beginning;—does not make its appearance, till the disease has existed for a length of time. The stuff which is vomited may be mere mucus; or it may be bile; or it may be like coffee-grounds; and sometimes the quantity is very considerable.

*The Intestines.*—The intestines likewise suffer in this disease. There is often more or less costiveness; but very often there is diarrhœa. Sometimes the diarrhœa begins with the disease; and sometimes it will not come on, till the latter has existed for a certain period. The character of the stools is as various, as the character of the matters vomited. They may be very watery; or they may be

<sup>a</sup> Page 350.

<sup>b</sup> The boy would eat, at a meal, a pound and a half of beef-steaks, a large fowl, or a couple of rabbits; without, apparently, satisfying his appetite.—“*Medical Transactions, published by the College of Physicians, in London.*” Volume 5; Page 353.

<sup>c</sup> “Exclusively of several basons of sago and other slops.” (See the Volume and Page mentioned in the last note.)

<sup>d</sup> “Food, in his case, is a provocative to food; and his appetite is always increased by eating.”—Ovid’s “*Metamorphoses*,” Book 8; Fable 11; Lines 104 and 105.

<sup>e</sup> “He began cruelly to mangle his flesh with his teeth; and, with the view of nourishing his body, diminished it.”—Ovid’s “*Metamorphoses*,” Book 8; Fable 11; Lines 140 and 141.

mucous, or (as the common people say) slimy. They may be (in colour) yellow, greenish, or white. They may be exceedingly offensive; and perhaps bloody.

*The Brain.*—The functions of the brain are almost always affected. Pain, vertigo, and tinnitus aurium, are very common; and sometimes there are convulsions, dulness, or stupor; there is usually great depression of spirits; and there may be delirium at night, terrific dreams, and watchfulness.

*The Breathing.*—It is said, with regard to respiration, that more oxygen is consumed in the hot stage of fever (as well as during digestion and exercise) than in health; and that more carbonic acid is formed; whereas, in the cold stage (as, indeed, after bleeding, and in dyspnœa) less oxygen is consumed, and less carbonic acid formed.

*Excitement.*—The disease, such as I have described it, may have all the symptoms of mere excitement, with no remarkable debility. There is always a feeling of more or less debility; but there may be sometimes chiefly excitement; and only that debility which is inseparable from fever. The fever may be subdued; the morbid changes which occur in the secretions and functions, may decline; nothing but weakness and a degree of emaciation may remain; and recovery from these may speedily take place. The emaciation, I may observe, is proportionately greater after fever, than after any other acute disease.

*Debility.*—However, this may not be the progress of the case. Signs of debility may appear; the breath may become very fœtid; as may also the perspiration, and all the discharges; whether from the stomach, the intestines, or the urinary bladder. What is vomited may be like coffee-grounds; the urine may be bloody; and so may the fœces. Even blood may be found in the mouth; or may be poured forth under the skin. There may be extreme blackness of the tongue; and a great quantity of sordes upon the teeth, lips, and every part of the mouth. All the fluids may be secreted in so vitiated a manner, that they may putrefy as soon as they are discharged; and the body may become putrid directly after death. One cannot conceive the possibility of putrefaction of parts still alive, or of the secretions at the moment of their formation; but they are often as near putridity as is compatible with life. The secretions putrefy, the moment they are separated from the body; and the body itself, as soon as it is dead, will frequently rush into great putridity. The discharges are sometimes so offensive, that perhaps the very house is intolerable. In these circumstances, the pulse is very rapid and very weak; there is extreme prostration of strength; and a death-like faintness is complained of by the patient. The face becomes ghastly;—in fact, we have the “*facies hippocratica*.” The intellect is greatly disturbed; there is an inability to attend to any thing; a troublesome hiccup; catching and working of the fingers (called “*subsultus tendinum*”<sup>a</sup>); perhaps convulsions; at any rate, cold clammy sweats; and an involuntary discharge of the urine and fœces. Still, the debility and putrescency may decline; and a high degree of these symptoms be recovered from.

*Varieties.*—If the symptoms be purely inflammatory,—purely those of excitement, with good strength at first, and do not afterwards degenerate into debility, or at least not into considerable debility, the disease is called “*synocha*.” If they degenerate into great debility, it is called “*synochus*.” If, from the very first, great symptoms of debility appear, it has been called “*typhus*.”<sup>b</sup> These are arbitrary names;—the two first having the same etymology;<sup>c</sup> but they do very well to express different characters of the same disease, in different individuals. When it is called “*typhus*,” it is the same fever as many authors write of under the name “*ship-fever*,” “*hospital-fever*,” “*gaol-fever*,” “*putrid-fever*,” or “*adynamic*<sup>d</sup> fever.” If the symptoms be very severe indeed, then it is called “*typhus gravior*,” but if they be mild, though it even prove fatal, it is then called “*typhus minor*,”—typhus being divided into two varieties. There is every variety in continued fever; both as to the degree of excitement and the degree of strength;—from

<sup>a</sup> “Leaping of the tendons.”

<sup>c</sup> They are derived from *συνεχῶς*, to continue.

<sup>d</sup> From *α* (privative), *without*; and *δυναμις*, power.

<sup>b</sup> From *τυφῶ*, to smoulder.

the very highest excitement, and a high degree of strength, down to the most absolute prostration that can be present; and from no putrescency, up to a high degree of it.

*Duration.*—The duration of the disease,—whether active and inflammatory, or of great debility and even putrescency,—may exist from one or a few days, to several weeks; but it rarely extends beyond eight or ten weeks. Occasionally the disease will end with a discharge of blood, either from the nose, the intestines, or other parts; or with purging or sweating. Dr. Gregory<sup>a</sup> said that he once knew a fever terminate by a great discharge of healthy urine. Andral says that he once saw a fever terminate with a profuse expectoration; and once with an alternation of sweating and expectoration. Suppuration after the disease, a general crop of petechiæ, and even the emaciation which follows the disease, are mentioned by authors as happy terminations;—as critical circumstances, which were closely connected with the happy result of the affection.

*Critical Days.*—These discharges, when they occur, are called “critical;” and the amendment is called “a crisis.”<sup>b</sup> The ancients imagined that a crisis occurred particularly on certain days: and hence those days were called “critical.” During the first eleven days of fever, these critical days were of a *tertian* character; so that the third, fifth, seventh, ninth, and eleventh days, were critical days; and were supposed to be those, on which the disease was supposed to terminate well. After the eleventh day, the type was supposed to be *quartan*; so that the fourteenth, the seventeenth, and twentieth days, were then supposed to be critical. If a change took place, it was supposed to be most favourable and most complete when it occurred on those days. It might happen on other days; but it was then supposed to be less favourable. Some are of opinion that the testimony of Hippocrates and Galen, among the ancients, and of Dr. Fordyce,<sup>c</sup> Dr. Stoker, and Dr. Percival,<sup>d</sup> among the moderns, in favour of these critical days, is too great to be withstood; but others imagine that it was a mere hypothesis, founded upon the Pythagorean doctrine of numbers; or that it was taken from the types of *intermittent* fever, which the ancients supposed *continued* fever must very much resemble. De Haen says, that of one hundred and sixty-three terminations of fever mentioned by Hippocrates, one hundred and seven (that is, two-thirds) took place on the critical days;—namely, on the third, fifth, seventh, ninth, eleventh, fourteenth, seventeenth, and twentieth; that none took place on the second or thirtieth; and only eighteen (that is, one-ninth) on the other non-critical days;—namely, the eighth, tenth, twelfth, fifteenth, sixteenth, eighteenth, and nineteenth. The only types of fever now talked of here,<sup>e</sup> are those of fourteen and twenty-one days;—so that the common people will say, that a patient has a fourteen, or a twenty-one day fever. Perhaps the vulgar only retain notions which formerly prevailed among physicians. Physicians may have inherited these notions from the ancients; and so they may have come down to us, and still linger among the vulgar. The notion *may* be correct. Some persons say they do observe these things; but I cannot say that I have ever noticed the disease to terminate on one day, in preference to another. The reason that we do not observe what the ancients did, is said to be, that we are more active in practice than they were. We do not let nature take her course, but endeavour to knock a morbid process on the head; and we cure far more cases of fever than they did. We allow diseases to run on a much shorter period, than they were accustomed to do; and some ascribe the want of critical days to our active practice. To show the inefficacy of the practice of the ancients, Broussais mentions that Hippocrates, in the first and third sections of his work on Epidemics, gives an account of thirty cases of acute disease; in which cases sixteen of the patients died, and the other fourteen suffered much afterwards. It must have been bad practice to

<sup>a</sup> See Note to Page 239.

<sup>b</sup> From *crasis*, the separation of something from the body.

<sup>c</sup> See his “Dissertations on Fever.”

<sup>d</sup> “Practical Observations on Typhus Fever; by Edward Percival, M. B.”

<sup>e</sup> In London.

lose sixteen acute cases out of thirty, unless in particular circumstances;—such as in the eastern epidemic, improperly called “cholera-morbus.” Sir Gilbert Blane says, that, in the first and third sections of Hippocrates, forty-two cases of acute disease are mentioned; thirty-seven of which were continued fever *without* local affection, and five *with* local affection. Of these twenty-five died;—twenty-one out of the thirty-seven, and four out of the five. If nature had an inclination to perform her cures on certain days, she had there a fine opportunity; but at the present day we so interrupt her course, that I have never observed critical days.

## SECTION II.—LOCAL COMPLICATIONS.

The parts most dangerously disturbed in fever, are the head, the chest, and the abdomen. The relative proportion of disturbance, in these different regions, is exceedingly various; but the head and abdomen suffer most of the three; except where there is a particular epidemic character; or an individual predisposition to, or a local cause of excitement in the chest. With these exceptions, the head and the abdomen suffer far more, in continued fever, than the thorax. It is in hot climates, and in hot seasons, that the abdomen is most affected. The local disturbance, when very great, is usually of an inflammatory kind;—at least it is usually inflammatory at first. But as there are all degrees of the general affection, from tonic to atonic, so the local affections may be of all degrees of violence;—varying from active tonic inflammation, down to mere irritation, or extreme loss of power.

*Cerebral Complications.*—To begin with the *head*. The local affection there, when very great, may give rise (as I have said before\*) to drowsiness, headache, convulsions, vertigo, watchfulness, and tinnitus aurium. But it may amount to a higher degree than this; so that we have violent headache,—such as distracts the patient; violent throbbing, which is visible when you look at the temples; intolerance of light; redness of the eyes; and violent delirium. The delirium may be constant; and it may be such as to require corporeal restraint. There may be loud, incessant, incoherent ravings; and ignorance of persons and things, which before were perfectly familiar to the individual; and yet, in the midst of this, a person may be rational and sensible for a single moment;—he may be momentarily recalled by some circumstance, but is instantly off again. At the same time, there is a picking of the bed-clothes, and tremor. Delirium of this description, is called “*delirium ferox*.”<sup>b</sup> On the other hand, the delirium is sometimes not of this ferocious character. The patient mutters to himself; there are altogether slighter symptoms of disturbance of the head; and it is then called “*delirium mite*.”<sup>c</sup> Occasionally, where there is great debility, there are no symptoms of vascular excitement in the head;—no headache, no intolerance of light, no redness of the eyes, or throbbing of the temples; but merely muttering delirium. Sometimes there is great stupor, and a comatose state; with or without symptoms of an inflammatory disposition in the head.

*Abdominal Complications.*—As to the *stomach*, there is almost always anorexia,<sup>d</sup> vomiting, purging, or costiveness, but these symptoms are sometimes extreme. There may be copious and intense vomiting of every thing that is taken, and of fluids of all descriptions. There may be violent diarrhœa,—of all kinds of characters. The abdomen may be excessively tender to the touch, and painful on the slightest pressure. It may be exceedingly distended; and may be especially painful at the epigastrium, or in the hepatic region. There may be a sense of burning in the abdomen, more particularly at the epigastrium; it may be felt likewise up the throat, and be attended by extreme thirst. When the symptoms in the abdomen run high, they are extreme vomiting, extreme purging, extreme tenderness, and perhaps violent pain, even when compression is not employed.

The state of the *tongue* has been supposed to correspond with that of the ali-

\* See Page 288.

<sup>a</sup> “Gentle delirium.”

<sup>b</sup> “Fierce delirium.”

<sup>c</sup> From *av*, *without*; and *αρεξικ*, *appetite*.

mentary canal. When the internal coat of the stomach is inflamed, the tongue is often, perhaps generally, red;—either throughout, at the edges, or at the tip; but the agreement in the two organs is not constant. The tongue may be red in fever, and in other diseases, without any corresponding state of the stomach;—at least, without any *evidence* of it; and therefore the alleged universal correspondence is a mere assumption. A blackness of the tongue is rather indicative of the general debility of fever, than of a gastric affection. Thirst may be commensurate with a gastric affection; but it may arise simply from the intensity of fever drying the fancies. Again: ulceration and inflammation of the stomach or intestines have been found, where the tongue had not been red during life; and it is said that sometimes neither they, nor any abdominal inflammation, could be discovered, where there had been much pain of the abdomen experienced on pressure. Purging may be very violent without inflammation of the mucous membrane; which may be found healthy in consistence, and even pale;—just as we have profuse sweating in various circumstances, without any inflammation of the skin. It is not a necessary circumstance that the tongue should indicate the state of the stomach or the intestines. There is a certain correspondence between them; but it is by no means invariable. Neither is it a necessary consequence that, when we see great irritation of the stomach, and great irritation of the intestines, there should be inflammation. Frequently, after such circumstances have occurred, inspections have not shown that inflammation existed.

*Thoracic Complications.*—As to the *chest*, it is commonly a little affected. In general, we have the breathing more or less quickened; and there is a little cough; and generally, if the ear or the stethoscope be employed, we find some degree of sonorous, or sibilous, or mucous rattle in the lungs. The symptoms may not be such as to attract the attention of the patient, or the practitioner, or to demand any measures; but if we listen with the stethoscope, I believe we shall generally find the mucous membrane of the bronchia more or less affected. Sometimes, however, the respiration is very *much* affected. It becomes very rapid; and there is violent cough; pain in the side, or at the front of the chest; great rattle; copious expectoration; and all the decided signs of bronchitic, pleuritic, or peripneumonic affection;—so that, at last, there is blueness of the lips and cheek,—from congestion of the lungs. I believe that, throughout the disease, there is more *congestion* in the lungs than actual *inflammation*. The affection of the chest, though it generally exists, is far less frequently of an inflammatory nature, than the affection either of the head, or the abdomen; and, of these two, the abdomen suffers most.

*The Blood.*—If we examine the *blood*, we may find it buffed, and perhaps cupped; but frequently it is quite natural. Sometimes the coagulum is exceedingly loose,—corresponding with the debility; and frequently it soon putrefies. In the typhoid stage of exhaustion and debility, it has been found that the chemical characters of the blood are very depraved;—that it abounds more and more in serum, and less in its other constituents. As the disease is more and more characterized by debility, the blood at last resembles mere fibrin and serum. Little or no chyle is formed, and the blood is deficient in carbonic acid, and in saline materials. Dr. Clanny, of Sunderland, pointed out this circumstance; and Dr. Stevens made similar observations. He made them in a distant locality,<sup>a</sup> without knowing what Dr. Clanny had done;—so that we have the unbiassed observations of two physicians, unknown to each other.

[The modifications of the blood in fever and many other diseases have lately been investigated by Andral and Gavaret, whose conclusions are highly interesting. These gentlemen found that the composition of this fluid in fevers was very different from what is met with in inflammations. In the latter the proportion of fibrin is increased, whilst the globules retain their normal standard, or are diminished in amount, but rarely augmented. In fevers, on the other hand, which do not depend upon local inflammation, such as continued fever and the exanth-

<sup>a</sup> London.

maata, the fibrin either retains its normal proportion or its diminished, whilst the quantity of the red globules remains the same or is augmented. In typhoid fever, (the common continued fever of Paris,) at whatever stage the blood was examined, the fibrin was never found to be augmented; sometimes its proportion was natural, whilst at others it was diminished, thus presenting conditions exactly the reverse of those which belong to inflammation. In the latter, too, the fibrin augments in exact proportion to the intensity of the disease, whilst in typhoid fever, on the other hand, the fibrin diminishes in the same proportion. Its quantity may fall as low as 0.9. Again, contrary to what occurs in inflammation, there is in typhoid fever, a tendency to increase of the red globules, and the earlier the stage at which the blood is examined, the more often are cases met with, in which not only are the globules not diminished, but very decidedly augmented in proportion. These alterations in the composition of the blood in fever, assist in explaining its imperfect coagulation and the softness of the clot. It is reasonable also to conclude that the frequent congestions of the spleen and other parenchymatous organs in fever, as well as the tendency to hæmorrhages and gangrene, are largely dependent upon the altered condition of the blood, for M. Magendie has found that in animals, hæmorrhages and congestions occur in proportion to the degree in which the quantity of fibrin is diminished.—[T. S.]

*Other Complications.*—Besides those particular parts that I have now mentioned, others are sometimes very much affected. Sometimes the eyes will become inflamed; and sometimes the throat, bladder, or skin. Sometimes we have an eruption of minute vesicles, of the size of millet-seeds; sometimes we have large patches of inflammation; sometimes we have irregular pimples,—papulæ. Occasionally we have a great discharge of blood from the intestines, and urinary passages; and perhaps all this without any correspondent severity of the general symptoms. Sometimes we have inflammation of the parotid glands;—ending in abscess. Occasionally abscesses will form in different parts; and sometimes a great crop of boils will appear. Now and then mortification of some part occurs;—not general mortification within the head, chest, or abdomen (the parts which are affected with *inflammation* in these cases); but mortification of the extremities, or of the loins. The debility is such, in this disease, that from a patient's lying long on his back, the loins are much disposed to mortify; and so may one or both hips. There being universal debility, the effect of pressure is not resisted, as it is when we are in health. If we lie upon a part, for any length of time, in health, it will not produce mortification; whereas persons in the debility occasioned by fever, from lying on their back, will soon have the circulation sufficiently impeded by the pressure to cause mortification. After fever, the mind will sometimes remain dull, or even imbecile, for a length of time;—sometimes for several months; and sometimes there is a great depression of spirits; which the patient, although in other respects pretty well, cannot shake off. Sometimes a hand or a foot, or both hands and both feet, or a whole extremity, will remain for a longer or shorter time bent, and little influenced by volition;—so that, indeed, a person is perhaps a cripple for life. I have seen several persons, whose hands or feet have been bent up in this way, after fever; and where this state ceased after a time; but I know others, in whom this state of parts continued many years, and continues still.

### SECTION III.—MORBID APPEARANCES.

The appearances after death will vary exceedingly. They are chiefly situated in the head, chest, and abdomen;—occasionally in *one* of these parts, occasionally in *two*, and occasionally in *all*; and, in all these parts, they will sometimes vary, both in their positive degree, and their relative proportion. The appearances vary:—from those of active inflammation, down to very slight marks of inflammation indeed;—where the case has been one rather of irritation than of inflammation; and they are sometimes those, not merely of ulceration, but of gangrene, or an

extreme degree of softening. The morbid appearances are chiefly found in the head and abdomen;—just as the local symptoms during life are principally situated there; and occasionally we find degeneration of the structure of parts, without much inflammation;—exactly as (I remarked<sup>a</sup>) is often the case independently of fever. We have softening, and various other changes, without any marks of inflammation at all proportionate to those changes.

*Appearances in the Brain.*—We will begin with the *head*. We sometimes find, in the brain, more red points than usual. We sometimes find the arachnoid injected;—both as to its superficial portion, and as to that portion which lines the ventricles. The veins and sinuses are frequently found turgid; and frequently there is too much serous fluid upon the brain, and in its cavities. But it must be remembered that, in all this, there is great room for fanciful opinion. On opening the brain, some will maintain that it is very healthy; and others will contend that there are more bloody points than there ought to be;—that the veins and sinuses are too full; or that there is more serous fluid than natural. We must take care, therefore, to be quite sure we are right, when we assert that any thing preternatural is found in the cavity of the head. It will continually happen in fever, that there shall be rather more bloody points than usual; without the patient, during life, having shown particular symptoms of an affection of the head. These appearances will vary in different individuals, even in health;—exactly as appearances do in other parts of the body. To enable us to say that there are decided inflammatory marks about the head, we ought to see appearances respecting which no one would entertain a doubt. When two or three persons differ in opinion, we ought to be much upon our guard in supposing that there is really any morbid appearance. I know there is so much fancy in all these things, that it is absolutely necessary to exercise the greatest caution in drawing a conclusion. But sometimes we do find, in fever, more bloody points than natural in the substance of the brain. The vessels of the pia mater are sometimes really in a state of congestion; sometimes the sinuses; and sometimes we find more fluid, indisputably, than ought to be there. This fluid is various in its appearance;—as in all other cases of affection of the head. Sometimes it is clear; sometimes turbid; sometimes fragments of lymph may be seen floating in it; now and then there is even effusion of blood, or (at any rate) the serum is bloody. But very often in fever, after there has been strong phrenitis, or strong marks of excitement of the head, we find nothing. I have repeatedly opened patients, who have died with marks of affection of the head, in whom the appearances after death have been quite disproportionate to the symptoms which occurred during life; and others in which I doubt whether any one, unprepared to *expect* any thing in the head, would have *found* any thing. Indeed, it is said by Andral, that the morbid appearances in the head, are less than those in the abdomen; and I believe this to be the case.

*Appearances in the Thorax.*—If the *chest* happen to be the part very much affected, (which is rarely the case,) then we have far more morbid appearances in the chest than in the head; notwithstanding that many have said, that the disease is situated in the head. If the thorax happen to show marks of disease, we may find the lungs soft;—we may find them filled with a frothy red fluid; and sometimes they will crepitate as in health, and sometimes not. Sometimes they will be soft, and quite impervious to the air,—especially if there have been extreme debility; and sometimes, but very rarely, they are in a state of gangrene. It is very rare to find them in a state of solidification, or what is strangely called “*hepatization*.”<sup>b</sup> Now and then we find them solid and gray in different parts;—spots of gray solidification; and it is common to find an abundance of red frothy fluid in them. One of the most frequent appearances in the chest, is redness and thickening of the bronchial tubes, because a slight degree of bronchitis is very common in fever. Now and then the pleura is affected. An effusion is observed in the pleura; perhaps redness of the membrane; perhaps adhesions;—at any rate an effusion of

<sup>a</sup> See Page 179.

<sup>b</sup> From *h<sup>ep</sup>ag*, the liver.

lymph. Now and then even blood is found. The appearances, in fact, bear an analogy to those which are found in the head. The blood which is found in the heart and large vessels, is generally fluid, and of a very dark colour. As to the coats of the arteries being inflamed, that we shall not necessarily find to be the case; though some have said that in fever they are always inflamed. The inner coats of the arteries may be inflamed now and then, like other parts; but we may open scores of bodies, and find no such thing. In one case, the coronary arteries were ossified; and yet the patient had no symptoms of angina pectoris; which is said to occur when the coronary arteries are ossified.

*Appearances in the Abdomen.*—If we come to the *abdomen*, we shall sometimes find marks of inflammation of the peritonæum, or at least of the sub-peritonæal cellular membrane;—or we may find inflammation within the stomach and intestines. The intestines are in general contracted, whether inflamed or not; but inflammation in the intestines is very common as well as in the stomach; and is situated in the cellular membrane under the muscular coat, or in the mucous membrane itself. It has been long known that, in fever, the intestines are very frequently inflamed. Theophilus Bonetus, an old writer, says that inspections of those who died of intermittent fever, showed that the stomach and intestines were inflamed. (“Anatome eorum qui febre malignâ extincti sunt, docet ventriculorum cum intestinis inflammari.”<sup>a</sup>) Bartholini bore testimony to the same fact:—“In omni febre acuta, imminet ventriculi inflammatio.”<sup>b</sup> Sydenham says that the intestines are frequently ulcerated in continued fever.<sup>c</sup> The knowledge of inflammation existing in the intestines, and also other affections, is not altogether new; though the fact was neglected. When the intestines are opened, we frequently find very extensive redness; and the redness will sometimes end suddenly, as inflammation of the skin will do; and sometimes it is lost insensibly in the surrounding parts. Occasionally we find the redness extensive,—running the length of a foot or so; but generally it is found merely in patches. Occasionally this redness is arborescent, and has little red spots around it. The redness varies in hue, from a bright red to a brown, or even a purple shade,—according to the degree of congestion; and sometimes it is a very dark red. In continued fever, the mucous coat is often thickened, and it may be thickened to a great extent, or only in patches. Sometimes it is softened; and, indeed, all the coats of the intestines are sometimes in the same condition,—softened. On the inner surface of the intestines,—the mucous membrane,—there are frequently small, red, conical elevations,—pimples; like the fringes below the tongue; or little white projections, either conical, or with a central depression. These last appearances are observed much more in the inferior two-fifths of the small intestines, than elsewhere; indeed, it is in this situation that we find the chief morbid appearances. In the colon they are generally pointed. Occasionally, these white conical elevations are real pustules; or, at least, small follicles containing real pus;—so that we have what may be considered pustules.

The secretion of the intestines is diseased. The mucus is of a thicker quality than it should be;—sometimes almost as thick as fibrin; and sometimes it is bloody. The mucous membrane will frequently peel off; not from any affection of its own, but from the cellular membrane which attaches it to the next coat being so brittle, as no longer to form a medium of union. Very frequently a quantity of blood is effused into the cellular membrane, under the mucous coat. Nothing is more common than to find ecchymosis;<sup>d</sup>—an effusion of blood into the cellular membrane, under the mucous coat.

*Ulceration of the Intestines.*—Ulcerations are continually found in the lowest third of the ileum, nearest to the cæcum; and the nearer to the cæcum, the greater is the degree of ulceration. I just now mentioned the frequent occurrence of red

<sup>a</sup> “Sepulcretum, sive Anatomia Practica.”

<sup>b</sup> “In every acute fever, the stomach is in imminent danger of inflammation.”

<sup>c</sup> See his “Opera Medica.” This work has been translated by Dr. G. Wallis.

<sup>d</sup> From *εκχυμωμα*, derived from *εκχυνω*, to pour out.

patches. In the midst of these, there is frequently ulceration; and then, again, the surface beyond the patches is frequently pale. It would seem that superficial inflammation had taken place locally, with great severity; and in the centre had proceeded to ulceration. But these ulcers frequently occur, also, in the little pimples or pustules of the glands; so that we have, in the intestines, two kinds of ulceration;—the one superficial, giving the idea of an abrasion (such as occurs in the mouth, throat, or on the organs of generation); and the other occurring in the glands. These ulcerations are of all sizes, and of all shapes. A portion is sometimes ulcerated to a very great extent; and sometimes these ulcerations are sloughy; or, at least, we may detach a sloughy layer of something;—perhaps sometimes a diseased secretion; and underneath we find an ulcer. Surrounding the glandular ulceration, we frequently see the mucous membrane more or less detached; and the ulcer, of course, extends to various depths.

*Perforation.*—Sometimes it extends so deeply, as to go through all the coats, and perforate the peritonæum. When this occurs, there is generally sudden peritonitis induced. Pain is felt at a particular spot, and darts from it in all directions; and speedy death generally ensues. Nature, however, sometimes prevents this (as I formerly said<sup>a</sup>) by producing adhesion; or perhaps the perforation is blocked up by a piece of omentum, or something else; but if this do not occur, violent peritonitis takes place, though not always. Occasionally the inflammation which is produced, is of a slow, chronic form. The patient recovers from the fever, but continues to labour under peritonitis, in a chronic form. Occasionally there is no pain; but this is rare. Generally, when a perforation occurs in the peritonæum, violent peritonitis is induced; and the patient sinks. Now and then, we have an abscess in the *substance* of the intestines;—in their cellular membrane, I presume. It occurs there as it does in the cellular membrane anywhere else. The peritonæal and the mucous coats being sound, the matter is produced between them; and is contained in the cellular coat. With respect to inflammation of the *muscular* coat of the intestines, I do not believe that such a thing occurs. Mucous, cellular, and serous membranes, are far more frequently inflamed than muscles. It is rare for muscles to be inflamed; and there is sufficient of the former structures in the intestines to become inflamed, without supposing that the muscular coat is the seat of inflammation.

The period at which these ulcerations may take place, is very various. It would appear that, occasionally, they will take place rapidly; because persons have shown them who have only had fever a couple of days; but generally they occur slowly. They are more frequently observed in persons who die of fever, than in those who fall victims to other complaints. The large intestines are seldom affected;—at least, far less so than the stomach or the small intestines; and of the latter, it is in that portion nearest the cæcum,—the lowest third of the ileum, or at the utmost the lowest two-fifths,—that we chiefly find these appearances.<sup>b</sup>

*Splenic Disease.*—I have in my possession a curious specimen of diseased spleen;—showing intense ossification. The peritonæal coat is exceedingly thickened;—so much so that it has become absolutely white. It is not only thickened, so as to have become almost cartilaginous; but there is a rare occurrence within. The blood-vessels (I presume, the arteries) are ossified. On passing the fingers over any of these vessels, the coats of the vessels are felt to be bony. There is another curious circumstance. Ulceration has taken place in the peritonæal coat of the spleen; which is rather a rare thing; though sometimes we see ulceration beginning in a serous membrane, and going inwards. In general, ulceration proceeds outwards (as is the case in ulceration of the intestines), till at last the peritonæal coat is ulcerated; but here the external coat of the spleen is alone ulcerated;—there being no ulceration beneath it.

*State of the Muscles.*—In fever attended with extreme exhaustion, the muscles

<sup>a</sup> See Page 71.

<sup>b</sup> The various morbid appearances here described, as occurring in the intestines, are well represented in Dr. Carswell's plates.

(I believe) are generally soft and livid. The blood, I mentioned,<sup>a</sup> is generally fluid and black in the large vessels; and the muscles are generally soft and livid;—a fact altogether corresponding with the state of the blood. I mentioned<sup>b</sup> that if, in a case of typhus-fever, where there is great prostration of strength, the blood be analyzed, it will be found to contain less saline matter than should be there; and it is said to contain less carbonic acid than natural;—in fact, it is more like lymph than blood. The liver and spleen are rarely affected. The bile is often abundant, and sometimes very dark and thick; but in other cases it is just the reverse;—pale and thin. Sometimes it is acrid, and sometimes not. The liver or spleen may exhibit marks of inflammation; or, if not inflamed at the time, the *results* of inflammation may be seen;—in the form of a little suppuration, &c. The organs in question may be softened. But all these things are very uncertain.

#### SECTION IV.—DIAGNOSIS AND PROGNOSIS.

*Diagnosis.*—We form our diagnosis, and determine that the case is one of fever, in a great measure, by observing that the constitutional symptoms are disproportionate to any local affection which may exist. The constitutional symptoms are, of course, influenced by a local affection; but they are out of all proportion to it; and frequently they are altogether of a different nature. For example: there is often to be discovered no local sign of inflammation, or of any local disorganization; but there is extreme debility from the very first;—a sense of debility, indeed, which is not observed in any mere inflammation. The countenance, too, is peculiar;—expressive of both anxiety and oppression. There is almost always, from the first, pain of the loins; and, nearly throughout the disease, tremor of the tongue. All these circumstances are very different from those which we see, in mere inflammation of the brain, or of the chest. Sometimes there is a local inflammation of the liver, or of the stomach; but we have also a disproportionate loss of strength; perhaps a feeble pulse; perhaps a putrescent state of the body;—symptoms, in fact, of a character different to those which arise from mere local inflammation. The countenance, and the sense of debility, are very characteristic from the very first.

*Prognosis.*—The prognosis must be taken, in the first place, from the severity of the disease; but we need not give an unfavourable prognosis, because the constitutional symptoms of excitement are very violent. Here *general* excitement is by no means dangerous; but when it is accompanied by extreme *local* excitement, —by marks of severe local inflammation, then there is reason to apprehend danger. As long as we can discover no great marks of inflammation in the head, chest, or abdomen, the general excitement, however violent, is not in itself dangerous. But although we have no right to infer danger from extreme excitement, when there is no great local affection, yet symptoms of an opposite description are always dangerous. In proportion to the intensity of the signs of debility, is the degree of danger. Intensity of general excitement, is not alarming in proportion to the excitement; but the danger is proportionate to the marks of real debility.

The marks of debility, in fever, are great rapidity and weakness of pulse. Andral says that he never knew a person recover from fever, whose pulse exceeded 140; but I believe it is well known that recovery will take place after a pulse even of 160,—however dangerous such a pulse may be. Dr. Heberden mentions recovery from fever, after a pulse of 180. If rapidity of pulse be accompanied by weakness, then of course the danger is so much the greater. Involuntary discharges of the urine and fæces, likewise, show great danger; because they prove extreme debility; or extreme local affection (of the head or abdomen, for instance). They will arise from the patient being unconscious of what he is about,—from being in a state of stupor; and they will also arise from the patient being too feeble

<sup>a</sup> See Page 294.

<sup>b</sup> See Page 291.

to make an effort to restrain them; either of which conditions is extremely dangerous. We learn much, too, from the position of the patient. When a patient lies on his back, there is more danger than when he lies on his side;—a greater effort being required to maintain the latter posture; but if the patient sink in his bed, the danger is greater still; for it then shows that he has very little power at all. A person can exert the muscles of deglutition, long after he has lost control over those of the trunk; and an inability to swallow, therefore, is one of the most dangerous symptoms. The countenance, I have already intimated, is a good index to the degree of danger. Blackness of the tongue, and of the teeth, is also more or less dangerous. We see patients recover every day, whose teeth have been covered with sordes, and whose tongue has been black; but still it is a bad sign. Abundance of the discharges, too, is generally dangerous, unless the symptoms remit; and the danger increases in proportion to their depraved nature. Another very unfavourable symptom is the discharge of blood, or its effusion under the skin;—forming petechiæ, vibices, and ecchymoses. The larger these spots, the greater the danger;—vibices being more dangerous than petechiæ; and ecchymoses more dangerous than vibices. Still, however, the presence of petechiæ in itself is not dangerous; for some epidemics are characterized by it; but if it be very considerable, and accompanied by other marks of exhaustion, then it is dangerous. Hiccup, too, is a dangerous symptom; on account of its usually coming on towards the fatal termination of the disease; but, now and then, fever may attack dyspeptic persons; and we may have hiccup, not so much from fever, as from the disposition to it occasioned by the habitually weak stomach. Early debility is a very unfavourable sign. Debility, after the disease has existed for a fortnight or three weeks, would not be so dangerous as the same degree of debility at the beginning of the disease; because, if the affection be to last for a fortnight, and there is at the beginning the same debility which, in other cases, we have at the end of a fortnight, the debility may be such when the latter period arrives, that life may be extinguished. The more intense the debility, in the early stage of the disease, the greater is the degree of danger to be apprehended.

When a person has violent pleuritis, peripneumonia, enteritis, peritonitis, or any other local inflammation, the danger is aggravated; and the danger frequently rests solely upon this local affection. The age and constitution of the patient, are important considerations. Individuals of bad constitutions, who have been badly fed, or addicted to the vice of drinking, or have suffered from the want of proper rest, are very liable to fall victims to the disease. We must always consider the character of the epidemic; for if we know it to be of a dangerous nature, we should always give an unfavourable prognosis even at the outset, before dangerous symptoms have come on. We are sometimes obliged to give an unfavourable prognosis, from the state of the patient's mind. I have often seen patients die of fever solely because their mind was uneasy. I have seen two or three patients, within the last six months, who in all probability would have recovered from fever, had it not been for an unfortunate state of mind. If a patient has made up his mind that he shall die, or some real calamity presses upon him, then the medical man has a far less chance of success, than if his mind be in a state of happiness and tranquillity. If we know this to be the state of the patient's mind, we should speak with more caution, even though things are going on favourably, than we otherwise should; for we have an additional enemy to contend with. We must also, in giving a prognosis, have reference to the power which we possess of doing our duty. Sometimes—through the whims of friends, or the unwillingness of the patient—we are not allowed to do what we desire; and sometimes we are prevented, by another practitioner, from being quite as active in the use of means as we wish. These things are all to be taken into the account.

*Favourable Prognosis.*—The grounds of a favourable prognosis, are furnished by the decline of all the symptoms. But we must be on our guard, when the symptoms are declining generally; and ascertain whether all is well throughout the body;—whether there may not be still existing some local circumstance, from

which danger may be apprehended. For example: fever will sometimes decline when the loins slough; and the patient may then die of exhaustion. A return of strength is one of the best signs. When a patient no longer sinks in bed, but is able to lie on his side, then the prognosis is favourable. We judge much from the countenance, and from the feelings of the patient himself. It has been thought that deafness is a favourable sign;—at any rate, it is *not* an unfavourable sign. Many authors have thought it favourable; but why it should be so, I do not know. In many cases of fever, patients become very deaf; and they recover, just as though this circumstance had not occurred. The return of all the feelings of the patient to a state of health, must contribute to a favourable prognosis.

## SECTION V.—CAUSES.

### *a. Remote Causes.*

*Predisposing Causes.*—I will not enter upon the *exciting* causes of fever now; but will speedily run over the *predisposing* causes; and the first I shall mention is mental depression. Many persons do not become the subjects of fever (though exposed to all the exciting causes) till their mind is depressed. I have known many persons go, year after year, to spots where fever prevailed (from some local circumstance) with perfect impunity, till some calamity happened which greatly depressed their minds, and then they became the subjects of fever. It has been observed, with regard to the plague, that persons have not fallen victims to the disease, till they have lost a relative, or been cast down in spirits; and then they have sickened immediately. Diemerbroeck mentions an instance of this kind. A person escaped the plague, till he saw a funeral pass by; and, on inquiring who it was, he found that it was one of his dearest friends. He went home, sickened of the plague, and died. The same circumstance occurs with regard to fever, and all other complaints. Anxiety of mind will have the same effect;—downright grief, or anxiety lest misfortune should occur. Corporeal depression, and over-exertion of mind, will have the same injurious tendency. Too much muscular exertion, excess of venery, and debilitating circumstances of all descriptions, whether of mind or body, will lay the foundation for fever. The *want* of food, and *bad* food, are both predisposing causes. Famine and fever generally go together; and hence, perhaps, we pray in the same breath against “plague, pestilence, and famine.”<sup>a</sup> Want of fresh air also predisposes to it. Adult age (or, at least, the vigorous period of it) appears the most inclined to it; for infants, and very aged persons, have fever less frequently than others. It is in adults, and not in the aged, that we most frequently see fever. Besides this, there appears to be a peculiar susceptibility to it in some persons: they will, with no evident reason, become the victims of fever, when placed in the same circumstances in which others escape.

*Exciting Causes.*—Some of the *predisposing* causes of fever may, by their continuance, become *exciting* causes. It is possible that the continuance of debauchery may, without any additional exciting cause, increase the disposition so much, that at least the disease itself begins;—requiring nothing at all, in addition to the debauchery, to produce it. One cause, certainly, of continued fever, is exposure to cold; especially when the body is over-heated. Many cases of fever appear to have nothing to do with any other exciting cause than exposure to cold, especially when this is united with wet; and more particularly when the body is over-heated and fatigued. Besides these very common causes of continued fever, there is generally allowed to be one of a peculiar description;—contagion.<sup>b</sup> Before considering this point, however, it will be necessary to make some remarks on the subject of contagion in general.

<sup>a</sup> See the Litany of the Church of England.

<sup>b</sup> From “*contingo*,” to touch.

### b. Contagion.

*Definition.*—By “contagion” is generally meant, I believe, either a peculiar matter generated *in*, or a depraved secretion *of*, a living system under disease; capable of producing the same disease in others, when there is *no indisposition* to it; and more especially if there be a *predisposition*.

*Nature of the Contagious Matter.*—I have said—“either a *peculiar matter* or a *depraved secretion*,” because, in the greater number of instances of contagion, it is a depraved secretion. Very frequently it is pus; as in the case of small-pox, syphilis, glanders, and a variety of other diseases. In the case of hydrophobia, it is either mucus or saliva; and in other instances it is apparently mucus. In the case of the skin, it sometimes appears to be sweat; but, for what we know, it may be sometimes separated from the body, unconnected with the real natural secretions of the latter. It is possible that an emanation of some kind may take place from the surface of the body, or the lungs, and infect the air, independently of the aqueous fluid which is separated from those organs; but whether such is the case I do not know. To avoid, however, the objections of those who admit such a thing, I think it better to say that it is “*either a peculiar matter, or a depraved secretion.*” I have said—“*living system*,” instead of “*animal system*,” in order to avoid the objections of those who might urge, that contagion occurs in vegetables, as well as in animals; and of course it is the characteristic,—the necessary attribute of a contagion, that it should be able to produce the very same disease in others. Not that it can produce it in *all* others; because there are some that will not take a particular contagion; but it is able to produce it in others, who have a *predisposition* to it; or rather, I should say, who have *no indisposition* to it. I said—“*others*” (referring to the antecedent phrase—“*living system*”), because contagions produced by one species of animals have, in many instances, affected other species; for there are several diseases of the inferior animals (“*brutes*,” as they are called), which may be communicated to the human body. It is necessary to say, therefore,—“*produced in a living system; and capable of exciting the same disease in another living system;*”—not of the *same species* merely; but “*another living system,*”—speaking at large.

*Nature of the Diseases produced by Contagion.*—When diseases are so produced, they may be (in the first place) either *acute* or *chronic*. What are called “the exanthemata,” are acute diseases; such as scarlet-fever, measles, small-pox, chicken-pox, cow-pock, and the plague; and so are hydrophobia and typhus (if the latter be a contagious disease); whereas the itch, syphilis, porrigo elephantisias, the yaws, the sibbens, and a disease (peculiar to Africa) called “*laander*,” always become chronic if not checked; and are not more active at first than afterwards. Some contagious diseases may be considered both acute and chronic. The hooping-cough (if it be a contagious disease) comes on, usually, as an active disease,—with all the activity of the most acute diseases; and yet it may run on for a length of time; so that it may be either acute or chronic; whereas scarlet-fever, measles, small-pox, chicken-pox, hydrophobia, and typhus-fever, cannot be chronic;—they are always acute. Syphilis, which I mentioned as being a *chronic* affection, cannot indeed be so considered when it first begins; but it rarely has, comparatively, the activity which characterizes acute diseases. Hooping-cough, however, is generally active at the onset; and frequently it has the activity of small-pox or measles; but it may run on for many weeks,—perhaps even months. Contagious diseases, both acute and chronic, are sometimes *febrile*, and sometimes *non-febrile*; and therefore it is better to divide them into “*acute*” and “*chronic*.” Hydrophobia is an instance of an *acute* disease of a contagious kind; but it is not in the least *febrile*.

Now, although we may put each of these diseases into one class or other of those I have been enumerating, yet it does not follow that a disease which is placed with another in *one* class, will be side by side with it in *another* class. These classes are all distinct;—the characteristics of each have no relation to those of another. The diseases which meet in one class, will not meet in another; and

the affections which are of different classes in one respect, will meet in another class with others. For example: hydrophobia is of the class of acute contagious diseases, together with small-pox;—both are acute diseases. But small-pox is in the class of those which may be communicated either by the atmosphere or by contact; whereas hydrophobia is in the class of those that can be communicated only by contact,—by the application of palpable matter. Itch and syphilis meet in the class of those that can be communicated by contact only; yet there is no reason to believe that the latter occurs *de novo*; while, I think, we have some reason to believe that the former does. The cow-pock is in the class of those which can be communicated by contact only; and so is itch; yet cow-pock is in the class, also, of those which occur but once; whereas the itch is in the class of those which recur indefinitely. Hence we see that the classes have no relation whatever to each other.

*Mode of Communication.*—Some of these diseases must be communicated by contact, either with the patient, or something that he has touched; or some palpable matter that has proceeded from him. Of this kind are itch, syphilis, cow-pock, hydrophobia, elephantiasis, yaws, sibbens, laander,—the three latter of which I have never seen,—and the glanders of horses; together, in all probability, with the plague, and porrigio or scald-head. Some, again, may be communicated both by contact, and merely by the atmosphere surrounding the patient. In the latter case, there must be the contact of something which has emanated from the patient; but then that something has not emanated in a palpable form. It is not the contact of any solid, or any liquid, that is to be *seen*; but the contact of something *invisible*. Still, that something must have proceeded from the patient. The diseases which may be communicated both by contact with the patient, and by contact with something he has touched, or something palpable which has proceeded from him; or which may be communicated by merely being exposed to his atmosphere,—are the small-pox, the chicken-pox, scarlatina, and the measles. The latter have certainly been communicated by inoculation;—just like small-pox. It is probable that, by means of something in the atmosphere which is not palpable, but which has emanated from the patient, we may become the subjects of typhus,—if it be a contagious disease,—and of hooping-cough. Even if an individual touch another labouring under these diseases, still it is probably not the mere contact, but an impalpable emanation from the patient, that gives the disease.

*Difference between Infection and Contagion.*—The adjective “contagious” embraces all the diseases we have enumerated; but it is also employed, in a restricted signification, to distinguish those which are communicated solely by contact with the patient, or with something that he has touched, or with something that has proceeded from him *palpably*; whereas the word “infectious” is given to those diseases, which may be communicated by merely being exposed to the patient’s atmosphere. The word “contagious” is used in the same way as the term “horse.” The latter is used to include both a horse and a mare; but it is frequently applied to the male only; and so these diseases are all continually spoken of as “contagious;” but the word “contagious” is also employed in a limited sense, to signify those diseases which are communicated by actual contact; or by touching something which the patient has touched; or something which has palpably proceeded from him. We sometimes hear quibbles on this subject; but it appears to me that the word “contagious” is used as I have now stated;—that we may separately have a contagious and an infectious disease; but that we may express them both, according to established custom, by the word “contagious.”

*Diseases are Communicated more Rapidly by Contagion.*—Some diseases are both contagious and infectious;—may be communicated either by contact (as I have already said), or by merely being in the neighbourhood of the patient. Now it is observed, that when a disease may be communicated in both ways, it is communicable more quickly by contagion, than by infection. If two persons be exposed to an atmosphere infected with small-pox, and we inoculate one with the virus, the disease will appear in him much sooner than in the other. It is a well-ascertained

fact, I think, that contagion (in the limited sense of the word) excites the disease sooner than infection, when the disease may be produced in both ways. Hence, when a person is exposed to the infection of small-pox, it is the practice to inoculate him as quickly as possible;—in order to bring the disease on in the artificial manner, before it can arise by infection.

*Diseases occasionally Contagious.*—Again: some diseases are thought to be only *occasionally* contagious;—I use the word “contagious” generically. Catarrh is supposed, by many, to be sometimes infectious; but I do not know whether it is so. Ophthalmia certainly appears to be sometimes contagious. In the greater number of cases it is not; but it would appear, undoubtedly, to be contagious in certain cases. Erysipelas is not considered to be a contagious disease; but Dr. Wells, in a paper published in the “Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge,”<sup>a</sup> furnishes very strong reasons for suspecting that certain instances which he details, were instances of erysipelas by contagion. Continued fever may be an instance of the same kind. It arises, certainly, very often, without contagion; but I am very much disposed to think that, in other cases, it is contagious.

*Contagion Limited in Time.*—Some diseases, again, are contagious only *for a time*. This is the case with gonorrhœa, and with hooping-cough. There is no doubt that, after a certain time, the discharge from the urethra (whether called “gonorrhœa” or “gleet”) is perfectly innocuous,—can communicate no disease. It is the same with hooping-cough. Children will continue to hoop, long after there remains any chance of communicating the disease to others. It is said that some diseases are only *partially* contagious. The instance of this which is usually alleged, is syphilis. The matter from the primary sores of syphilis, will communicate the disease. It is contagious enough; but it is said that the matter of secondary sores is not contagious. It is impossible to make experiments on this subject; and, therefore, I cannot tell whether those who hold this opinion are correct or not.

*Contagions generated afresh.*—Some contagions appear to be occasionally generated afresh. Some of those diseases which will give rise to a something capable of producing the disease in others, do appear to be produced *de novo*. The itch, at any rate, will sometimes occur in patients after continued fever, where it is not possible to trace it to any other persons. Hydrophobia, there is every reason to believe, will sometimes spring up in the same way. Dogs become the subjects of the disease, without its being in our power to trace it to any other animal;—where there is no probability of their having been exposed to contagion. The same is true of the glanders in horses. This is also said to be the case with regard to typhus;—that a patient has become the subject of it, from a mere common exciting cause; and that he has been known to give it to others. Of this I cannot speak; because I never saw typhus fever contagious. With regard to all these diseases,—itch, hydrophobia, and typhus (granting the latter to be contagious), whether or not they ever now occur *de novo*, still they must have had that origin at some time or other; and it is not more wonderful for them to occur *de novo* now, than that they were originally produced. There must have been a person who first had measles, small-pox, scarlet-fever, and so on; and who could not have derived it from any other person. If we even go to brutes, still the difficulty is the same; for some of them must have had the disease first of all. It must have occurred *de novo*, in some one instance or other. Indeed, it is not certain that small-pox, chicken-pox, hooping-cough, scarlet-fever, and measles, do not occur, from time to time, without contagion. We frequently see these diseases in children who have been shut up in the country; without having had communication, directly or indirectly, with any others who could have had them; or having been near persons who had visited others suffering the affection;—at least, so far as we

can trace it. It is possible, however, that an error may exist on this point; and that there *has* been communication; but, certainly, the ascertainable absence of all communication, direct or indirect, occurs so often, that I do not think we have a right to assert, that the diseases in question never occur *de novo*. I give no opinion on the subject; but I would not be positive on the negative side.

*Recurrence of Contagious Diseases.*—Some contagious diseases occur rarely more than once. Among them we may mention cow-pock, chicken-pox, small-pox, measles, hooping-cough (by which I mean the real disease,—not a spasmodic hoop), and scarlet-fever. We must all have seen instances of a second occurrence of these affections, and sometimes perhaps of a third; but the general rule is for them to take place but once; while the rest may occur more than once; and, indeed, some of them an indefinite number of times. Some persons contract syphilis and gonorrhœa over and over again;—as long as they expose themselves. It would not answer the moral end of these complaints, were they (like small-pox and measles) to be had but once. With regard to hydrophobia, it is not known whether it may be had twice or not. So far as I am acquainted with the subject, both human beings and dogs have always died of the disease when seized with it; and, therefore, we cannot tell whether it may be had a second time.

*One Contagious Disease renders the Body insusceptible of Another.*—Another circumstance I may mention is, that we have an instance (or, at least, we *generally* have an instance) of one contagious disease preventing another. The cow-pock is supposed to prevent the small-pox; and, for the most part, it certainly does; but it is to be considered, that it is not by any means proved, that cow-pock and small-pox are not the same disease;—the former being modified. If they be but one disease, the fact of cow-pock preventing small-pox merely resolves itself into the fact, that some contagious diseases do not usually occur more than once; but if they be distinct diseases, then it is an instance of one contagious disease preventing another.

*Period of Incubation.*—When a contagion has been applied, there is for the most part an interval before it operates;—there is usually an interval, between the application of the poison and the appearance of the disease. This interval is various in different diseases; and it is various in different cases of the same disease;—depending upon whether it is applied by means of the atmosphere, or in a palpable form by inoculation. The interval of small-pox is very short, compared with the interval of hydrophobia; and then, again, the interval of the latter is by no means always the same. It will vary, from a few weeks to a few months.

*Infection prevented by Dilution.*—Some of these contagious diseases which are infectious,—using the word “contagious” in a generic sense, to comprise both, are very easily prevented by dilution of the atmosphere. We find a great difference in diseases, in this respect. The contagiousness of diseases which are infectious, or the *infection* of some diseases, is very easily annihilated by dilution; whereas great dilution has comparatively little effect on others. The infection of small-pox, and of measles, will sometimes operate in a very free ventilation. It is thought, by some, that their infection will not extend to a very great distance in pure air. But, at any rate, in the *purest* air, we see these diseases caught by children, in the neighbourhood of those that labour under them; whereas other diseases cannot be caught, if any pains at all be taken to dilute the air. As a remarkable example of this, I may mention that the contagion of continued fever (if continued fever be allowed to be contagious) may be dissipated with the greatest ease. A comparatively trifling dilution of the atmosphere around the patient, will prevent it from being communicated to any one; whereas a great dilution will frequently not prevent the small-pox or the measles. So easily is the contagion of continued fever (supposing it to be contagious) dissipated, that if there be a very free ventilation around the patient, there is little or no danger of any one catching the disease; and it is asserted that, in small-pox, the contagion, in the worst cases, will not extend beyond half a yard, in the open air. Dr. Haygarth, in his cele-

brated letter to Dr. Percival,\* says that the infection of small-pox will not extend beyond the distance of half a yard; and that of continued fever much less; and this is one reason why the contagious property of the latter has been denied altogether.

*Contagious Diseases communicable to Brutes.*—Some contagious diseases are communicated from brutes to man. Hydrophobia, cow-pock, and (it would appear) small-pox, are of this description. Every one knows that the cow-pock may be given to the human subject; but it is said that some experiments have lately been made, with success, to give the small-pox from the human subject to the cow; and these have been adduced as proofs that the two diseases are the same; because the disease produced in the cow by the *small-pox* matter, was the *cow-pock*. The itch is a disease communicable from brutes to man; at least, it is said that a kind of itch is produced from mangy dogs. There is a peculiar disease in Germany, mentioned under the name of "*milzbrand*,"—"inflammation of the melt." It is a disease of brutes, analogous to what has been called "malignant pustule;" and is communicable to the human subject. Many persons have had malignant pustules produced in them, by merely touching the blood of animals labouring under a certain disease; or, perhaps, by merely putting into their mouth a knife wetted with the blood. The glanders of the horse is another disease, which may be unquestionably communicated to the human subject. It is possible that all those diseases, which may be so communicated from brutes to man, may be given back from man to brutes. M. Magendie has made experiments with regard to hydrophobia. He inoculated dogs with the saliva of a man labouring under hydrophobia; and, he says, they became the subjects of the disease. The cow-pock, I believe, may be given from the human subject to brutes; and so, unquestionably, may the glanders. Whether any other contagious diseases than those I have enumerated, may be given from brutes to the human subject, I do not know; but I should think all these may be given back. It is said that there are some other diseases, which may be communicated from man to brutes. The plague, it is said, has affected brutes; sheep have been seen to catch the measles; and the disease called "*trichoma*" may also be communicated to brutes.

*Bad Health sometimes prevents Contagion.*—There are some contagious diseases, to which persons are very much disposed by being out of health;—typhus-fever for example; whereas, other contagions act as well upon persons in health as out of it. But it would appear that sometimes bad health will *prevent* a contagious disease. It is well known, I believe, among vaccinators, that they frequently cannot give a child the cow-pock, when it is labouring under any cutaneous affection. It is found by many who vaccinate to a great extent, that they cannot give a child the cow-pock, when it is labouring under any disease, such as scald-head, or any chronic eruption. This may simply arise from the body being indisposed to take on two diseases at once;—not that the body is out of health altogether; for, a cutaneous disease is but a *slight* affection. Habit lessens the susceptibility to some contagions; at any rate, persons who are continually exposed to the infection of typhus-fever, in its most concentrated form, generally escape; and so with respect to the plague. A new comer into some situations, will sometimes suffer immediately; while those who have been accustomed to it will go on with impunity, and never suffer. Habit appears to have a great influence upon contagion;—just as it has with regard to the aguish effect of marsh-miasmata.

*Insusceptibility of different Persons and Ages to Contagion.*—Some persons have an unaccountable indisposition to contagions. Some children will not take the small-pox, though they sleep in the same room, and even in the same bed, with others labouring under it. The same has been observed with regard to the measles; and (what is very singular) after a lapse of time,—sometimes a year or two, and sometimes longer,—the least exposure will produce the disease in the same indi-

\* "Letter to Dr. Percival, on the Prevention of Infectious Fevers; by John Haygarth, M. D."

vidual. It is well known that some persons run into the greatest risks, with respect to syphilis and gonorrhœa, without using any precaution; and invariably escape, though as bad as their neighbours. In fact, I have known persons of that description; and yet, after a time, they began to catch the disease whenever they ran the chance of so doing. It is the same with respect to small-pox and measles in young persons, as it is with regard to syphilis and gonorrhœa in adults. The extremes of age are very insusceptible of many infections. Some persons, again, without any indisposition (so far as can be observed) escape, without our knowing why. A person shall be exposed, for example, to the poison of syphilis to-day,—the existence of morbid secretion being proved by the fact that others, yesterday or to-morrow, suffer from the same source,—and catch nothing; and yet, a fortnight afterwards, the same source may give the disease to him. Persons without any indisposition sometimes do escape, without our knowing why.

*Existence of Contagion Denied.*—Some persons deny there is any such a thing as contagion. Some deny the contagiousness of one disease, and some of another; but there are some who maintain, that contagion was unknown in ancient times, and is altogether a modern invention. There is (or was) one person so convinced of this (in the case of hydrophobia), that he has written a pamphlet to prove it. He contends that it is a mere imaginary disease; that, at any rate, the symptoms which have occurred, have never taken place *through hydrophobia*. He says that he has inoculated himself, again and again, with the saliva of a rabid animal; and has escaped. His escape, however, is no proof of the non-existence of contagion; because many persons escape all sorts of contagions, every day. Two medical students, at Paris, went so far as to deny that syphilis was contagious; and, in the year 1823, they inoculated themselves with some syphilitic matter. They laughed at contagion; and gloried in having some syphilitic matter under the skin. However, the consequence of this experiment was a very bad suppuration in, and a partial destruction of, the axilla of one young man;—he having inoculated himself on the hand; while the other had a bad ulcer somewhere else; and became so distracted at what had happened, that he actually committed suicide, by opening the crural artery. Others have done exactly the same in the case of the plague; and they have suffered exactly in the same way. A Dr. Whyte was convinced that the plague was not a contagious disease; and, therefore, in the pest-house of the Indian army at El Hammel, he rubbed some pus, taken from the pestilential bubo of one of his patients, inside his own thigh; and, not contented with this, he inoculated his wrist from another pestilential bubo. Four days had hardly passed, before rigors began; with all the symptoms of violent fever; and he died of plague before the end of the third day. It is mentioned, in the “*Journal de Medecine*” for May, 1811, that an Italian doctor (called Dr. Valli), was so convinced of the non-contagiousness of the plague, that he mixed the matter from some pestilential buboes with a number of other things, and formed it into an ointment, which he called his “pomade.” He rubbed this mixture on the eyelids of people who came to him with sore eyes; on the abdomen of others, &c.; and thereby communicated the plague to thirty individuals. He was quite sure that he was doing no harm whatever. The Turks, however, thought differently; for, disapproving his practice, they cut off his head.

There are on record some other singular instances, of the denial of what it would appear almost impossible that any one would think of denying. Dr. Maclean, for instance, denied that plague was contagious: and went so far as to explain why it, or any other disease, was ever supposed to be contagious. He says that the idea of contagion is merely an invention comparatively modern;—that it was neither more nor less than a popish trick of 1547. He would have us believe, that one of the popes, Paul the Third, in 1547, (after the death of our King Henry the Eighth, of blessed memory,) when the holy fathers were assembled at Trent, finding he could not manage them,—that he could not get them to vote his own way, broke up the council by setting forth the idea of contagion:—that he stated there was a contagious disease in the town;—a disease that might be caught from those affected

with it; and thus excited so much fear among the members of the Council, that all withdrew to Bologna. Thus was the celebrated Council of Trent dissolved. The holy men were so frightened at this invention of his popeship, that away they all went scampering to Bologna.

The introductory part of Boccaccio's "*Decamerone*," contains a description of the plague at Florence.<sup>a</sup> He says, that the disease spread from the diseased to the

<sup>a</sup> In the year of our Lord, 1348, there happened at Florence, the finest city in all Italy, a most terrible plague; which—whether owing to the influence of the planets, or that it was sent from God as a just punishment for our sins—had broken out some years before in the Levant; and—after passing from place to place, and making incredible havoc all the way—had now reached the west; where—spite of all the means that art and human foresight could suggest (such as keeping the city clear from filth, and excluding all suspected persons); notwithstanding frequent consultations what else was to be done; nor omitting prayers to God in frequent processions—in the spring of the foregoing year [1347], it began to show itself in a sad and wonderful manner; and—different from what it had been in the east, where bleeding from the nose is the fatal prognostic—here there appeared certain tumours in the groin, or under the arm-pits; some as big as a small apple, others as an egg; and afterwards purple spots in most parts of the body; in some cases large and but few in number, in others less and more numerous;—both sorts the usual messengers of death. To the cure of this malady, neither medical knowledge, nor the power of drugs, was of any effect;—whether because the disease was in its own nature mortal, or that the physicians (the number of whom, taking quacks and women-pretenders into the account, was grown very great) could form no just idea of the cause, nor (consequently) ground a true method of cure. Which-ever was the reason, few or none escaped; but they generally died the third day from the first appearance of the symptoms; without a fever, or other bad circumstance attending. And the disease, by being communicated from the sick to the well, seemed daily to get ahead, and to rage the more;—as fire will do, by laying on fresh combustibles. Nor was it given by conversing with only or coming near the sick; but even by touching their clothes, or any thing that they had before touched. It is wonderful, what I am going to mention; which, had I not seen it with my own eyes, and were there not many witnesses to attest it besides myself, I should not venture to relate,—however credibly I might have been informed about it. Such, I say, was the quality of the pestilential matter, as to pass not only from man to man, but (what is more strange, and has been often known) that any thing belonging to the infected, if touched by any other creature, would certainly infect, and even kill that creature in a short space of time; and one instance of this kind I took particular notice of;—namely, that the rags of a poor man just dead, being thrown into the street, and two hogs—coming by at the same time, and rooting amongst them, and shaking them about in their mouths—in less than an hour turned round, and died on the spot. These accidents, and others of the like sort, occasioned various fears and devices amongst those people that survived,—all tending to the same uncharitable and cruel end; which was, to avoid the sick, and every thing that had been near them;—expecting, by that means, to save themselves. And some—holding it best to live temperately, and to avoid excesses of all kinds—made parties, and shut themselves up from the rest of the world;—eating and drinking moderately of the best, and diverting themselves with music, and such other entertainments as they might have within doors;—never listening to any thing that was without, to make them uneasy. Others maintained free living to be a better preservative; and would balk no appetite or passion they wished to gratify;—drinking and revelling incessantly from tavern to tavern, or in private houses; which were frequently found deserted by the owners, and therefore common to every one;—yet avoiding, with all this irregularity, to come near the infected. And such, at that time, was the public distress, that the laws, human and divine, were not regarded; for the officers to put them in force being either dead, sick, or in want of persons to assist them, every one did just as he pleased. A third sort of people chose a method between these two;—not confining themselves to rules of diet like the former, and yet avoiding the intemperance of the latter; but, eating and drinking what their appetites required, they walked everywhere with odours and nosegays to smell to;—as holding it best to corroborate the brain: for they supposed the whole atmosphere to be tainted with the stink of dead bodies; arising partly from the distemper itself, and partly from the fermenting of the medicines within them. Others, of a more cruel disposition,—as perhaps the more safe to themselves,—declared, that the only remedy was to avoid it. Persuaded, therefore, of this, and taking care for themselves only, men and women (in great numbers) left the city, their houses, relations, and effects; and fled into the country;—as if the wrath of God had been restrained to visit those only within the walls of the city; or else concluding, that none ought to stay in a place doomed to destruction. Divided as they were, neither did all die, nor all escape; but, falling sick indifferently,—as well those of one as of another opinion,—they who first set the example by forsaking others, languished themselves without mercy. I pass over the little regard that citizens and relations showed to each other, for their terror was such, that a brother even fled from his brother, a wife from her husband, and (what is more uncommon) a parent from its own child: on which account, numbers that fell sick could have no

healthy, as flames spread to an unctuous substance. Not only speaking and associating with each other produced it, but the clothes or any thing else that belonged to persons who laboured under the plague, communicated it. Even brutes got the disease, by touching the clothes of those who died of the plague. He says:—"I

help, but what the charity of friends (who were very few), or the avarice of servants supplied; and even these were scarce, and at extravagant wages; and so little used to the business, that they were fit only to reach what was called for, and observe when they died; and this desire of getting money often cost them their lives. From this desertion of friends and scarcity of servants, an unheard of custom prevailed. No lady, however young or handsome, would disdain being attended by a man-servant (whether young or old it mattered not); and to expose herself (naked) to him,—the necessity of the distemper requiring it,—as though it was to a woman; which might make those who recovered less modest for the time to come. Many lost their lives, who might have escaped, had they been looked after at all; so that—between the scarcity of servants, and the violence of the distemper—such numbers were continually dying, as made it terrible to hear, as well as to behold. Whence, from mere necessity, many customs were introduced, different from what had been before known in the city. It had been usual, as it now is, for the women who were friends and neighbours to the deceased, to meet together at his house, and to lament with his relations; at the same time, the men would get together at his door, with a number of clergy,—according to the person's circumstances; and the corpse was carried by people of his own rank, with the solemnity of tapers and singing, to that church where the person had desired to be buried; which custom was now laid aside; and—so far from having a crowd of women to lament over them—great numbers passed out of the world without a single person; and few had the tears of their friends at their departure; but those friends would laugh and make themselves merry; for even the women had learned to postpone every other concern to that of their lives. Nor was a corpse attended by more than ten, or a dozen; nor those citizens of credit, but fellows hired for the purpose; who would put themselves under the bier, and carry it with all possible haste to the nearest church; and the corpse was interred, without any great ceremony, where they could find room.

With regard to the lower sort, and many of a middling rank, the scene was still more affecting; for they, staying at home,—either through poverty, or hopes of succour in distress,—fell sick daily by thousands; and, having nobody to attend them, generally died. Some breathed their last in the streets, and others shut up in their own houses; when the stench that came from them made the first discovery of their deaths to the neighbourhood. And, indeed, every place was filled with the dead. A method now was taken (as well out of regard to the living, as pity for the dead) for the neighbours, assisted by what porters they could meet with, to clear all the houses, and lay the bodies at the doors; and, every morning, great numbers might be seen brought out in this manner; from whence they were carried away on biers, or tables, two or three at a time; and sometimes it has happened, that a wife and her husband, two or three brothers, and a father and a son, have been laid on together. It has been observed, also, whilst two or three priests have walked before a corpse with their crucifix, that two or three sets of porters have fallen in with them; and where they knew of but one, they have buried six, eight, or more. Nor was there any to follow and shed a few tears over them; for things were come to that pass, that men's lives were no more regarded than the lives of so many beasts. Hence it plainly appeared, that what the wisest in the ordinary course of things, and by a common train of calamity, could never be taught,—namely, to bear them patiently,—this, by the excess of those calamities, was now grown a familiar lesson to the most simple and unthinking. The consecrated ground no longer containing the numbers which were continually brought thither,—especially as they were desirous of laying every one in the parts allotted to their families,—they were forced to dig trenches, and to put them in by hundreds;—piling them up in rows, as goods are stored in a ship; and throwing in little earth, till they were filled to the top. Not to rake any further into the particulars of our misery, I shall observe, that it fared no better with the adjacent country; for—to omit the different castles about us, which presented the same view (in miniature) with the city—you might see the poor distressed labourers, with their families,—without either the plague, or physicians, or help of servants,—languishing on the highways, in the fields, and in their own houses, and dying rather like cattle than human creatures; and, growing dissolute in their manners (like the citizens), and careless of every thing (as supposing every day to be their last), their thoughts were not so much employed how to improve their substance, as to make use of it for their present support: whence it happened, that the flocks, herds, &c., and the dogs themselves (ever faithful to their masters), being driven from their own homes, would wander—no regard being had to them—among the forsaken harvest; and many times, after they had filled themselves in the day, would return of their own accord, like rational creatures, at night. What can I say more, if I return to the city?—unless that it is supposed, and made pretty certain, that, between March and July following, upwards of a hundred thousand souls perished in the city only; whereas, before that calamity, it was not supposed to contain so many inhabitants. What magnificent dwellings, what noble palaces, were then depopulated to the last person! What families extinct! What riches and vast possessions left, and no known heir to inherit! What numbers, of both sexes, in

saw two pigs grubbing about the clothes of a man who died of the plague; they then staggered and fell down dead.” (“*Amendui sopra gli mal tirati stracci morti caddero in terra.*”<sup>a</sup>) This was actually published in 1348; and yet a man would seriously have us believe, that the idea of contagion was invented in 1547.

However, some are more hardy than this. They will deny almost all sorts of contagion. There is a M. Lassis, of Paris, who denies all infections and contagions, except those of measles and lues venerea. But this is by no means a modern folly. I imagine that some of these persons have hoped to signalize themselves by advancing something original, when they denied this or the other contagion; and particularly that those who deny many contagions, or nearly all, must have thirsted for fame indeed. But they are too late. They are merely dull imitators; for many persons among the older writers have denied, sometimes one contagion, and sometimes another. Gadbury, the astrologer, says that the *plague* is not *more infectious* than the small-pox, scurvy, pleuritis, ague, and gout. He published in 1665; and his book is called “*London’s Delivery Predicted.*”

There can be no doubt, that great mistakes have been committed on the opposite side, as to the contagiousness of particular diseases. We have seen<sup>b</sup> that Dr. Fordyce and Dr. Cleghorn, both able men, believed that *ague* was contagious; and, when speaking of *scurvy*, I mentioned<sup>c</sup> that some contended, formerly, that that disease was contagious. We know now, to a certainty, that neither ague nor scurvy is contagious. Again: some diseases, on the other hand, which we now certainly know to be contagious, were not supposed to be so. It is by no means certain, from the writings of Sydenham, that he was aware that small-pox or scarlatina was contagious, or perhaps even measles. He may occasionally write as if they were, but he attributes them to other causes than contagion; and it is by no means clear that he was much impressed with the fact. But other writers refer small-pox, and other diseases just mentioned, to causes of all kinds instead of to contagion; such as the faults of parents, before their children were born or procreated;—any thing, in short, rather than contagion. Mistakes, it must be allowed, have been committed on both sides of the question. Diseases not contagious were formerly supposed to be so; and diseases known now to be contagious beyond all doubt, were formerly, at different periods, not imagined to be of that nature; and therefore we ought to listen, with some degree of patience, to those who deny that any particular disease is contagious.

*Is Typhus Contagious?*—Typhus-fever is a disease, which some deny to be contagious; and I willingly confess, that I never saw an instance in which it showed that character. Nevertheless, I cannot but believe that it is frequently a contagious disease. Such it has proved itself at the Fever-Hospital, at Battle Bridge. I do not recollect an instance of its spreading; notwithstanding the experience of many years, as physician to St. Thomas’s Hospital; where, of course, there is always a great deal of fever. But it is to be remembered, that the majority of cases of fever which are met with there, are generally by no means violent, compared with what (I am told) they are at such an institution as the Fever-Hospital. An exceedingly small number of cases of fever are lost at St. Thomas’s;—either because persons are admitted in the early stage, when the disease is easily treated and cured; or because they are not desperate cases that, in general, people think of taking there. I hear, however, that to the Fever-Hospital (which is a receptacle for this disease only) patients are taken, as a matter of course, when they have fever, whether moderately or desperately; and therefore many are so taken, of whom there is no hope that the disease will be cured. The greater success at

the prime and vigour of youth,—whom in the morning neither Galen, Hippocrates, nor Æsculapius himself, but would have declared in perfect health—after dining heartily with their friends here, have supped with their departed friends in the other world. But I am weary of recounting our late miseries.—*Translation of Boccaccio’s Introduction to his “Decamerone.”*

<sup>a</sup> “Both fell down dead upon the clothes about which they had grubbed.”

St. Thomas's, therefore, is owing (in a great measure) to the comparative mildness of the disease treated there. This may be one reason why the disease does not appear contagious there;—the emanations from the body are not of that extremely powerful kind, which they frequently are at the Fever-Hospital; and it is not *all* our patients, but a very small number, who labour under the disease. In the next place, we have extreme ventilation,—extreme cleanliness; and this is another reason why a *mild* disease, at any rate, will not spread. I have no doubt there is the same cleanliness and ventilation at the Fever-Hospital; but they must be infinitely less efficient there; because *all* the patients have fever; whereas with us generally but one or two, and rarely more than three patients with fever, are in the same ward;—large as our wards are. There can be no doubt that, if typhus-fever be very bad indeed, persons standing near the patient, even if there be good ventilation, may now and then contract the disease.

*Arguments for the Non-Contagion of Typhus.*—But with regard to the arguments in favour of typhus-fever not being contagious, it is to be remembered that it is a disease, the contagion of which may be most easily rendered quite inert, by the dilution of ventilation; unless in some very *very* bad instances, on the one hand; or where there is a great predisposition to it, on the other. In the next place it is a contagion, which is allowed by those who stand up for its contagiousness, to be resisted exceedingly, if the body be in good health, and the person be in good spirits. But it appears to me, that there are instances, without end, of a person catching typhus-fever from others. It is true, I have never met with one of these cases; but instances innumerable are mentioned, by those who see far more of the disease than I do; though I see quite as much as I wish;—perhaps about fifty cases in a year. There will also be found, recorded in books, cases without end;—such as I cannot pretend to controvert. I understand, with regard to the Fever-Hospital at Battle-Bridge, that every medical officer there,—physicians, surgeons, and apothecary,—have had the typhus-fever; and some more than once;—that every nurse, every matron, every laundress, every housemaid, and (in short) every body that ever had any thing to do with the place, have all had it; and many officers have died. Yet nothing of this kind has happened at the Small-Pox-Hospital, which is on the very same spot. This is very important;—as clearing up the point, whether all these persons have had it from the emanations of the patients there, or from the situation of the hospital. I used to see, every day, persons taken to St. Thomas's with typhus-fever, from the midst of others who have the disease; but I never considered that any proof of contagion. The disease *may* have arisen, in those cases, from contagion; but the fact is not *proved*; for it may have been the *situation* which gave rise to it. Some fault in the house—some drain, or other external cause—may have caused the disease, first in one patient, and then in another. For infection to be proved, the individual who communicates the disease must go from the place where he resides, to the spot where the healthy person is, and there give it to the latter. If the healthy person go to the sick person, and the sick person be still in the place where he was living when attacked, then no one can say that the disease, which the former contracts, has not been produced from the *situation*, and not from the *patient*. The disease *may* have arisen from contagion,—from the emanations of the patient; but this is not *proved*. If the patient go to a healthy spot, especially from an unhealthy one, and the disease then occurs there in others; or if any thing which the patient has touched, be taken from the place where the patient resides, to a healthy place, and there the disease takes place;—then it proves, if there be a sufficient number of these instances, that the disease is contagious. Many persons who have caught the fever at the hospital, have carried it home and given it to others, who had not gone near the hospital. Whether, however, this were the case or not, there are instances (without end) of persons having visited patients with the disease, and then given the disease to others where they have gone.

*Fomites.*—Inanimate substances have become impregnated with the secretions or emanations from a person labouring under a disease; and have communicated

the disease to other persons. All such substances are called "fomites."<sup>a</sup> Among these, woollen substances are by far the most influential. All woollen substances imbibe secretions and emanations, and convey infectious and contagious diseases, far more than any other description of substance. It will be recollected that, even in the case of malaria, some assert that bushes will entangle it; and, on cutting them down, persons have been seized with intermittent and remittent fevers;<sup>b</sup>—arising, in all probability, from the disengagement of a considerable quantity of malaria, which had been collected. Even the cutting down of woods,<sup>c</sup> will have the same effect; and therefore there is something analogous to fomites, in the case of malaria; but it is in cases of *contagion* that, to inanimate substances, the term "*fomites*" is applied. There are instances, without end, of the plague having been conveyed by old clothes. It is even said, that the plague of London was conveyed to Derby by that means. There is scarcely any point in medicine, of which there are more numerous instances, than of plague and typhus-fever having been conveyed by left-off clothes. The exanthemata are frequently so communicated; and when I come to speak particularly of yellow-fever, I shall be able to lay some instances before you, in which this has unquestionably been the case; although it would appear, from the testimony of one whom I have the pleasure to call my friend,<sup>c</sup> that yellow-fever is of different kinds;—that there are two kinds; one which is not contagious, and one that undoubtedly is so. I dare not say how long fomites will retain contagion. I know that a person who has been about another labouring under measles, will communicate the disease at the end of even a month; and that a room once infected with scarlatina, will give the disease for a twelvemonth. The contagiousness of fomites is best destroyed by heating them well.<sup>d</sup> Articles may be exposed to a high temperature; and large fires, with plenty of smoke, best disinfect apartments.

*Sudden Cessation of Typhus.*—Whenever such a thing occurs, as disease being produced in a healthy spot, by the approach of an unhealthy person to a healthy one, or the application of fomites to a healthy person, it is a proof of contagion;—provided the instances be sufficiently numerous; for one or two cases may be quite accidental. But an argument against the contagion of typhus-fever, is adduced from this circumstance;—that it will sometimes disappear during an extreme temperature; and will sometimes disappear altogether, without any obvious reason; whereas, if it were contagious (it is argued), it would spread from one to another; till all, or the greater part, suffered from it. It is said, that it is only a disease which depends upon a particular state of the atmosphere, and not upon an emanation from a diseased person; and that *therefore* it is suspended by the extremes of temperature, or will suddenly cease without any obvious reason. It is indeed true, that non-contagious yellow fever, and intermittent and remittent fevers, and other diseases decidedly not contagious, will be aggravated or repressed by extremes of temperature; and by causes not discoverable. But this is exactly the case, not only with typhus-fever, but with diseases which all people of common sense allow to be contagious. Epidemic small-pox is frequently checked by extreme cold. The plague, which (I believe) almost every body allows to be a contagious disease, in the strict sense of the word, (not *infectious*, but *contagious*;) is also stopped by extreme heat or cold. Small-pox is frequently so stopped; and also by the wind called "*harmattan*,"<sup>e</sup> which also arrests the plague; and (what is curious) this wind will prevent persons from *taking* the small-pox, even if they be inoculated. When that wind prevails, inoculation is commonly found to be fruitless. We have, therefore, the same fact with respect to diseases undoubtedly contagious, or infectious, or both, that we have with respect to such diseases as our remittent or intermittent fever: or others which depend upon something in the atmosphere, not proceeding from diseased persons. This objection, therefore, has no force. Hoop-

<sup>a</sup> From "*fomes*," *fuel*.

<sup>c</sup> Dr. Stevens.

<sup>d</sup> The experiments of the late Dr. Henry, of Manchester, have placed this fact in a very strong light.

<sup>e</sup> See Note to Page 255.

ing-cough and measles, which most persons allow to be contagious, are generally checked at the height of summer; and Sydenham says that scarlatina is most prevalent when the summer is over.

But there are still more remarkable facts, with respect to the stopping of diseases known to be contagious;—nay, of some diseases which are, not *infectious*, but *contagious* (in the true sense of the word). Cow-pock, which can only be communicated by contact, will sometimes decline so much that, at one period, Dr. Jenner could not prosecute his inquiries into the disease, for want of matter. Although there was apparently no reason for the disease not spreading as usual,—“in the natural way,” as it is said,—from the teat of a cow to the hand of the human subject, it was sometimes so checked, that Dr. Jenner could not obtain a case of it. When he was publishing his work on the subject,<sup>a</sup> the very same thing happened; and Dr. Woodville says, that the disease did not reappear till the following spring, at which time it chiefly prevails. Sometimes, without our knowing why, small-pox (an unquestionably contagious disease) will not affect a place quite contiguous to another; although it is prevailing in the one, and free intercourse is being carried on between them. Van Swieten mentions this; and Sir John Pringle says, that he saw small-pox carried by recruits into the camp; and yet it did not spread. Dr. Odier, of Geneva, inoculated children when the disease was not epidemic; and though they were going about the streets, every day, during the eruption of the disease, and although there was the freest communication between the children who had been inoculated and others, yet not a single instance was seen of the disease spreading. There was something (whatever its nature might be) in the atmosphere, that prevented it. Sir James M’Grigor says, that the small-pox was raging in houses at Bombay, contiguous to the barracks; and yet no child or adult in the latter place imbibed the disease. There was something in the situation which prevented it. In Burckhardt’s “Travels,” there is something equally curious on this point. This author says,—“It is a curious fact, but one which has been attested to me by many persons, that small-pox has never been known to visit the Wadykenous; which is a narrow shore, from the Cataract up to Korosko. But,” he adds, “this disease is well known at Derr; which is close by, and where it is much dreaded.” It was never known to pass a certain point, notwithstanding there was free intercourse.

If such singularities will occur in the case of diseases known to be contagious, there is no reason to doubt that typhus-fever is contagious, merely because it will suddenly cease in a neighbourhood, or in a district, without our knowing why; or because it may be apparently arrested by extremes of temperature. Not only will undoubtedly contagious diseases sometimes not spread in the natural way (to use common language) at certain seasons; but sometimes we cannot produce a disease, although we inoculate for it. It would appear to be the same in the case of hydrophobia. We sometimes hear of nothing but mad dogs. A mad dog is killed every day, sometimes, for a month; and then we never hear any more of the disease for a twelvemonth. Now one would suppose that the disease would be communicated from one to another easily enough; but it is impossible not to imagine that, at one period, there must be a far greater susceptibility to disease, than at another. There is no *a priori* objection, therefore, to the possibility of typhus-fever being contagious. The only question would be—“Is it a fact, or is it not?” I think there are sufficient instances—instances without end—of persons having communicated the disease to others. Provided there is plenty of dirt, bad living, unhealthy circumstances, and a want of free ventilation, I think there can be no question as to the disease frequently proving contagious. There is certainly a great difference of opinion on the subject; and it undoubtedly is not contagious to the extent that many believe; and great cleanliness, with plenty of ventilation, will so dissipate the disease, that no practitioner, if in good health and spirits, and well fed, need be

<sup>a</sup> “An Inquiry into the Causes and Effects of the Variolæ Vaccinæ; a Disease discovered in some of the Western Counties of England, particularly Gloucestershire, and known by the name of ‘The Cow-Pox.’ By Edward Jenner, M.D.”

afraid of it;—unless it exists in great intensity, and the emanations are applied to him in a concentrated state. In order to imbibe the disease, if the practitioner be in good health, and there is free ventilation, he must go so near to the patient, as to inhale his exhalations in full concentration; but if he be out of health, the disease intense, and ventilation indifferent, he may easily catch it. This must make a great difference in determining whether the disease is contagious or not; for there are very numerous instances, in which the disease does not appear to be contagious; yet it is to be considered that, in these cases, if the bystanders had been predisposed by debility, &c., and there had been no ventilation, it might then have proved contagious. The question, however, must be determined by a great number of cases.

An objection to the contagiousness of typhus-fever has been raised, not only from the irregularity of the period at which it begins, but from the irregularity of the duration of the disease; yet scarlatina, although undoubtedly a contagious disease, is very uncertain as to its course. Scarlatina will, in different instances, show the eruption at very different days. Sometimes the eruption will appear on the first day;—the very day on which the patient is taken ill; and sometimes it will appear before there is the least redness or soreness of the throat. Then,—when the eruption *does* appear, it will sometimes last only a day, or a day and a half, or two days; and sometimes it will continue ten days. No valid objection can be raised to the fact of typhus-fever being a contagious disease, merely because it is very various, not only as to the period at which it takes place, but also as to its duration; for scarlet-fever likewise exhibits these very same varieties. Nay, the same would also appear to be the case with regard to small-pox; for Sydenham speaks of an epidemic small-pox, in which the eruption took place on the fourth day; which is not the usual period at which it occurs.

*Causes which Facilitate or Retard the Contagion of Typhus.*—Granting, however, that it is contagious, there are various reasons for explaining the circumstance of its frequently not spreading far;—it may not be *always* contagious, but only *occasionally* so; like erysipelas, perhaps. Another reason is, that persons (for the most part) escape the influence of the contagion, if they be in good health and spirits while exposed to it. I presume that neither good health, nor good spirits, nor good nourishment, nor any other good thing, however favourable to health, will render a person less disposed to catch the small-pox, or to catch syphilis; but it is a fact, that if a person be in excellent health and spirits,—if he have every means of promoting health in his power,—if all be healthful in and about him, he may be exposed to the emanations of a person labouring under the most virulent typhus, and yet (for the most part) escape. If, however, his mind becomes depressed, or if his body become debilitated in any way, then we see the same person become the victim of the complaint, when exposed to the emanations of a typhous patient in so slight a degree, that we could hardly suppose it possible for the disease to be communicated. Many persons are exposed, with impunity, to the emanations from patients labouring under typhus, till their mind desponds, or (by some chance) they are thrown out of health; and then the contagion,—if typhus be contagious,—acts as a predisposing cause; and the depression of the mind, or the accidental depression of the bodily powers, acts as an *exciting* cause. We have seen<sup>a</sup> that, in the case of ague, a person may be exposed to malaria, and not contract the disease, till he gets cold and wet through;—the common original cause of the disease (the malaria) being the *predisposing*, and “catching cold” the *exciting* cause. Exactly so, in typhus, the peculiar contagion is often the *predisposing*, and depression the *exciting* cause. I mentioned<sup>b</sup> that, in the instance of the plague, persons have been known not to experience the disease, till they have lost some of their most intimate friends; and have thereby become depressed. Diemerbroeck, I stated,<sup>b</sup> mentions an instance of this kind; and there are hundreds similar.

These things are all to be considered, when we question whether continued fever

<sup>a</sup> At Page 266.

<sup>b</sup> At Page 298.

is contagious or not. It is allowed by those who contend for its contagiousness, that the contagion is one which is most easily dissipated by ventilation. In the next place, it is allowed by them, that if a person be in good health, and with every means of health in full play, he will generally escape; and if it be a fact that the disease is sometimes contagious, and sometimes not, and sometimes arises *de novo*, then we see another reason why some people have denied the contagion of the disease altogether. However, I am quite sure that much of the difference of opinion, on this subject, must have arisen from this circumstance;—that many diseases have been called “typhus,” which were no such thing. There can be no doubt that many of the cases of continued fever which we see, are really cases of *remittent* fever, dependent upon malaria;—having nothing at all to do with contagion. We every day see cases of remittent fever, mistaken for typhus, but easily distinguished from it by nice observers; and persons may be exposed to such cases, without suffering the disease; and therefore typhus is continually said not to be contagious; whereas the patient really labours under remittent fever, which is not a contagious complaint.

*Period of Incubation of Typhus.*—The interval which occurs between the application of the poison of typhus-fever, and the appearance of the disease, is exceedingly various;—exactly as occurs in other diseases. Dr. Haygarth says, that of seventy-two persons who were exposed to the contagion of typhus-fever, five were seized with the disease within ten days after exposure; thirteen were seized between the tenth and the seventeenth days; forty-one were seized between the seventeenth and the thirty-second day; and one so late as the seventy-second. This variation of interval, is the same as is observed with respect to all diseases acknowledged to be contagious. How long the poison may lie dormant, I cannot say; but to take a case from another poison,—malaria, we must remember that many months frequently elapse before ague is produced; so that the malaria becomes the *predisposing*, instead of the *exciting* cause; and the same may be the case, sometimes, with respect to typhus-fever. It may exist dormant for a length of time; but what is the utmost period it will do so, I cannot pretend to say. It must have a limit, of course; but we know not what that limit is.

*Confinement and Filth.*—But although the contagion of typhus-fever is rendered much more active by concentration, and both that and filth are injurious to a patient, and must render him more liable to be affected by the contagion, yet it frequently happens, that the utmost filth and the greatest closeness will not produce the disease. Some have ascribed the disease to confinement of air and to filth; and both these will unquestionably be injurious to the health at large; and contribute to render a person exposed to the contagion of typhus, the victim of the disease; yet persons are continually exposed to mere filth and confinement, without suffering. In Kamschatka, the people live (seven months in the year) in “yourts;” which are cavities dug seven or eight feet under ground, and covered with a thatched roof; and which have only one small apartment, for three families perhaps; with a stock of provisions, consisting chiefly of dried putrid fish. In these pits they eat, sleep, and do every thing promiscuously; so that there is the most intolerable stench; which, though not perceived by themselves, is but too evident to travellers. Yet they have no fever. On the contrary, they are all healthy; with the exception of being liable to scurvy, which arises from the want of fresh provisions. The Greenlanders and Esquimaux crowd themselves together, and exclude the air. They have no chimneys in their huts; but an inner apartment, the fog and smell of which are quite suffocating to strangers. Yet they very rarely have fever. In general, they only experience scurvy. The habitations of the Russian boors, are equally intolerable to strangers; and yet it is said, they never have putrid diseases. Dr. Lind says, that in the slave-ships crossing the Atlantic, although the poor creatures are crowded below deck as much as possible, and at night are shut up under close hatches; and, although they suffer from a change, and some are suffocated; yet (in general) they have no infection; and if an accidental infectious disease enters among them, it is of a much milder charac-

ter, than when it occurs in felons who had been transported in an opposite direction;—owing, probably, to the opposition of a high temperature to the contagion of typhus. It is said (but I do not know with what degree of truth) that contagious fever never occurs in these slave-ships. At the black-hole in Calcutta,—an apartment forming about a cube of eighteen feet; and only opening to the west, by two windows strongly barred,—one hundred and forty-six persons were confined (in the month of June, 1756) from seven or eight o'clock in the evening, till dawn the next day. One hundred and twenty-three individuals were suffocated; and the rest were, of course, made ill. It is said, however, that the survivors afterwards felt only heat and extreme exhaustion; that a great many had boils; but that no fever was produced. Howard (the philanthropist) says, that there was no fever in the prisons at Venice; though they were the closest possible. He also says, that the prisons at Naples were close and offensive; that the people were ill; but that no fever was produced. He adds, that we must look for an additional cause of fever, than mere filth and confinement. Dr. Mounsey says exactly the same of the prisons at Moscow and Petersburg; though the prisoners were crowded together, and had but little ventilation. But it is to be remembered that, when fever is introduced into such situations, it rages with the most dreadful violence; and it is also found that new comers into such filthy places, when contagion is present, suffer much more than those who have been habituated to them;—that contagion acts the more, on account of the bad state into which this filthy confinement throws the constitution. Those that were habituated to these situations, before the contagion was introduced, became gradually accustomed to it. People constantly live in confinement and stench, which would half poison us; but when strangers go into this filth, after having been in pure air, they are much more liable to experience the disease; and, if they suffer, it is worse in them than in others. Still, although, till certain contagions are introduced among people who live in close, dirty, and bad situations, they consider themselves as well as others differently situated; yet those contagions, when introduced, at once act as a test of the tendency of the previous mode of life; and these people suffer in an infinitely higher degree than others;—provided there be not present any accidental counteracting cause; such as great heat, in the case of typhous contagion. A mere surgical accident will test the previous mode of life, in two people who might have appeared equally healthy.

Persons have been crowded together in the most filthy prisons, where the discipline was frightful; where they were treated like beasts;—in a way that *we* should not think of treating beasts; and yet no fever was produced. Various authors give an account of a disease which broke out at Oxford, in the year 1577, in the reign of Queen Elizabeth; at what was called “the black assizes.” Some prisoners were brought out of prison, where they had been in a state of great confinement, with very little ventilation, and exceedingly dirty. A strong stench arose, and was supposed to proceed from the prisoners. Some of the judges and magistrates, the sheriff, and most of the jury, were taken ill; and died in a day or two. Six hundred persons sickened the same night; in the next three days, three hundred more sickened; and before five weeks had elapsed, five hundred and ten had died. The symptoms are said to have been violent pain of the head and abdomen, with delirium. Many contended that this was a disease produced by the confinement of these prisoners;—that a contagion was generated from them;—that although they did not suffer themselves, a contagion passed from them, and produced this disease. But others, of equal judgment, are of a different opinion; and urge, on the other hand, that the disease was not contagious. It is said that the court was held in the yard of the castle, that was only a small distance from the river Isis, the banks of which were low; and it is actually recorded that a great damp arose; that “a *breath*,” as it is called, or a *fog*, arose among the people; and that, at the same time, an intolerable stench was perceived; and some seemed smothered. The weather was intensely hot. The disease was not the plague; and the physicians would not name it. From all these circumstances, some writers

content that the disease had nothing to do with the prisoners; but that it was an exhalation, owing to the dampness of the earth;—some peculiar kind of exhalation; that we have no proof of its contagiousness; and that typhous contagion rarely affects so instantaneously. Women, children, and poor people, are said to have escaped. How this may be I do not know; but, to show the bigotry of the times, I may mention that others took up a very different opinion; and alleged that it was neither contagion nor exhalation; but entirely owing to the poor Roman Catholics, who used the art of magic. They stated that it arose from diabolical and papistical arts;—that it was produced by popish blasts, which emanated from the lowest depths of hell. This is particularly mentioned in Wood's "History of Oxford:"—"Some have thought, and do think, that it was devised by the Roman Catholics, who used art-magic in the design; and that also, as a certain note witnesseth, (Register of Merton College,) it sprung *ex artificiosis, diabolicis, et plane papisticis flatibus; e Lovanensi barathro excitatis; et ad nos scelestissime, et clam emissis.*"<sup>a</sup> This absurd opinion seemed favoured by the circumstance of a damp or fog having arisen in the court, as soon as sentence of loss of ears was passed upon a book-binder, who had continually spoken against Elizabeth's government, and the reformed religion.

Another singular instance occurred at the Old Bailey, in 1750; where several persons were taken ill, after the prisoners had been brought into court, subse- quently to close confinement. This has been supposed to be exactly a similar instance, but it appears that there are objections to it; and many contend that it arose from a window being open, and a draught of air coming on those who suffered. How this might be, I do not pretend to say; because there are many circumstances that might alter our opinion, if we had an opportunity of making minute inquiry. I can only state my belief, that typhus-fever is sometimes contagious; that it may be made so in very unfavourable circumstances;—that it is, perhaps, always contagious in one sense; only that the contagion is so mild and diluted, that it comes to nothing; and that it belongs, like cholera, to those contagions which are not only powerless when moderately diluted, but powerless upon a frame free from disease, in full vigour, and with all or most of the causes of good health about it. We know from Thucydides, that before the plague of Athens,—from Livy, that before the plague of Rome,—and from Hodges, that before our plague in 1665, great crowds were collected in each respective city; that, in the latter case, the sky was serene, and the air stagnant; and that the rich escaped so much, that the disease is said, by Clarendon, to have acquired the name of "the *poor man's* plague."

*Putrid Animal Matter.*—As mere confinement will not (in general) produce fever, without some predisposing cause, so dead putrid animal matter is also said to be innocuous, while unaided. An instance of the latter is adduced with respect to Paris. In the course of six centuries, there were six hundred thousand bodies buried in Saint Innocent's churchyard, in that city; and they were spread under ground over two acres. The soil, by this vast deposition, was raised above the streets; and there was an offensive smell; but no fever arose from it. They were partially removed, in the heat of summer, till the ground was levelled; and the workmen were frequently asphyxiated,—frequently fell down senseless; but none of them were attacked by fever, although no precaution was employed. It is said that, in Seville, there is a fetid odour from the ground where ten thousand bodies were deposited, during the time of an epidemic;—that the soil cracked, and great stench was produced, but no fever. Howard (the philanthropist) says that, at Smyrna, there was a most horrid smell from the burial-ground, after the plague; and many corpses lay uncovered; but no bad consequences ensued to the family of the governor, whose house was exposed to the exhalations from the spot. Dissecting-rooms will not produce fever; unless an individual be either exposed to contagion, or very much out of health;—through anxiety of mind, hard study, or some acci-

<sup>a</sup> "From artificial, diabolical, and evidently papistical blasts; stirred up from the pit [or hell] of Louvain; and privately and most wickedly directed against us."

dental circumstance. Persons attending a dissecting-room, will become out of health, and be ill, and perhaps die, from the very severe effects of slight wounds; but I am not aware that fever which will spread to others, has ever been produced in that way. Various diseases, confounded with fever, have been produced; but I am not aware that fever itself has so occurred, when there was no depressing passion,—no anxiety from over study, want of proper rest, or any kind of excess. Still if mere stench, unaided by other things, and through delicacy of constitution,—not counteracted by the presence of the ordinary causes of health,—should impair the latter, I can conceive that fever may be produced at last. Nightmen, as far as I know, are as healthy as other persons; and yet their grounds are certainly offensive enough. A spermaceti-manufactory, the stench of which was intolerable, existed near Bristol for two years; but no fever was produced. It is said that, at a manufactory (situated at Oldland, in Gloucestershire) where bones were employed for the purpose of procuring muriate of ammonia, an intolerable stench was produced; and yet no fever resulted from it. It is said that the superintendent removed to a more convenient house, situated upon a hill; and that there he and his family lost their health; so that he had some idea of returning back to the offensive place, that he might recover his health. At sugar-refineries, where blood is kept till it is putrid, persons do not suffer. Leather-dressers are exposed to offensive smells; and yet they escape. Many persons are employed in the most offensive occupations with putrid animal matter; and yet fever never breaks out amongst them, if they possess the general means of health, and are well fed and cheerful. But if these persons, in the midst of stench, were in a state of famine, and consequently in great depression of mind, then (in all probability) fever would occur. Those who are interested particularly with this point, will immediately remember the examples adduced by Mr. Thackrah, in his work on the diseases of the different occupations of life.\* Butchers are exposed to more or less stench; glue-manufacturers, buckram-makers, and tallow-chandlers, are all exposed to odours more or less offensive; and yet they enjoy excellent health;—are ten times more healthy than bakers. Orfila mentions the healthiness of knackeries; where there is immense putrefaction in summer, and the soil has been saturated for years.

To show that these exhalations do not hasten the decomposition of even dead animal matter, the following fact is mentioned. In the neighbourhood of a dissecting-room behind the Hôtel Dieu,—where the odour was so offensive that, after numerous petitions, the dissecting-room was removed,—ragouts, bouilli, and good things of all sorts kept as sweet in the midst of this horrid smell, as in any other situation. A veteran of the imperial guard (to mention another instance) turned gut maker; and said that, although his premises were truly offensive,—filled with enormous masses of corruption, yet nothing spoiled in his house. It cannot be denied, however, that although these things do not generate fever, yet they operate strongly when other causes come into play. Though they may all be thrown off, as water is from an oiled surface, when a person has no other cause of ill health, and is well supplied with good food, and has good spirits, yet they do produce mischief when other causes are combined with them. It is also to be insisted upon, that if actual contagion be introduced into a place which is offensive, then these things appear to tell; and the mischief is greater, on account of the closeness of the situation, and the exhalations from the putrefying animal matter.

It is therefore certain, I think, that mere confinement,—mere exposure to the emanations from persons crowded together amidst the greatest filth, will not in itself produce fever. I think it is quite certain that animal matter, in the greatest state of putrefaction, does not of itself afford any thing which will produce a disease called “contagious.” It may be that the persons so exposed are fed well; and are in good spirits; and have all other means of contributing to health at their command? Still, however, if any matter which is in a state of putrefaction,—as is, or was formerly, the case in dissecting-rooms; as occurs in ammonia-manufactories, and manufac-

\* See Note to Page 48.

tories and other places where putrid blood is used, and from which there are horribly offensive emanations;—if this alone could produce contagious diseases, we should have fever every day, where we have nothing but perfect health. There can be no doubt that, if these things throw a person out of health, then any contagion, or any other cause of fever, will act intensely in producing this disease. This is allowed with regard to cholera. Nobody believes that any putrid emanations, or any thing that proceeds from persons crowded together, or the putrefaction of animal matter, will produce that disease; but all know that these things have a tendency to throw people out of health; and by the body being thus brought into an unnatural state, it is rendered an easy prey to any other causes that are applied.

*Can the Contagion of Typhus be Generated Afresh?*—There is another question;—whether the contagion of typhus (allowing that it is a contagion) may be generated afresh? There is no proof that certain contagions can be generated afresh; but others unquestionably may. Want of good food, want of rest, closeness of situation, depression of spirits, and exposure to bad air, may (by all conspiring together) occasion fever; but whether they occasion *contagious* fever, I do not know. I have never seen an instance of it. I have seen many young men ill from close studying, together with being much in a dissecting-room;—especially when they came fresh from the country, and were not accustomed to a dissecting-room, or to hard study; and were very anxious about their studies. Young men, when about to pass examination,—their anxiety being then so much the more increased,—have certainly had fever; but I never saw their disease spread contagiously. Others say that they have seen it spread, in such circumstances. They tell us that typhus is a disease, the contagion of which may be generated *de novo*: but, though this is highly probable, yet one should always be cautious in listening to assertions in medicine; because so many assertions are made, without any ground whatever.

*Rarely Communicated by the Dead.*—The bodies of persons dead of typhus, rarely (if indeed ever) give the disease; and typhus, like other epidemics, whether contagious or not, grows milder and milder, the longer it lasts; although it be spreading more and more.

*Other Noxious Exhalations.*—Besides *malaria* being a cause of *remittent* and *intermittent* fever, and besides *contagion* being a cause of *continued* fever, it is very possible there are certain other exhalations, which do harm,—which produce actual disease. Sydenham had an idea, that epidemics arose from some peculiar changes in the bowels of the earth. It was only a fancy of his; but it is very possible that some of these peculiar causes of disease, are exhalations let loose from particular spots. Berzelius mentions a curious circumstance. He was making experiments with seleniuretted hydrogen; and, after a certain period, catarrh came on, and continued a very great length of time. A quantity which he inhaled, while making the experiment, did not produce any inconvenience *at first*;—but after a certain period had elapsed, then (as in the case of all specific poisons) it began to operate. Now some persons, from such facts as these, conceive that a volcano may let loose a substance, capable of producing a peculiar operation on the human body. It is not altogether improbable that exhalations, of various sorts, may arise out of the earth;—independently of the exhalations of diseased animal bodies; and independently of the exhalations, from the *surface* of the earth, of putrefying vegetable matter. The subject is not at all understood; but it is certainly an inquiry worthy of being attended to, whenever an opportunity occurs.

### c. Proximate Cause.

Having considered the *remote* causes, we next come to consider the *proximate* cause of fever; respecting which, there have been, I might say, thousands of hypotheses. In these hypotheses, the writer has generally assumed some one fact which had no existence; or has taken up one particular circumstance, from among all the circumstances of the disease, and placed that as the cause of the whole.

*Solidism and Humoralism.*—Some assume it as a fact, that the disease is all in the solids; others assume it as a fact, that it is all in the fluids. Those who ascribe every thing in a disease to the fluids, are said to be "*humoral* pathologists." Their fancy is this;—that a certain something is in the fluids, which is deleterious to the body; that a process, analogous to fermentation, is going on, which they call "concoction;" that the "peccant matter" is then separated, and the process is called "despumation;" and, provided it is thrown off entirely, there is an end of the disease. Now there is not the least proof of any such process occurring. There is proof of the depravation of the fluids; but there is no proof of concoction and despumation,—of a salutary fermenting and despumatory reform of the fluids (if I may so speak). There is nothing peculiar thrown off, when an excessive secretion takes place; as at the crises when great diarrhœa or sweating occurs; or at least, if there be, we know it not; and it is a mere fancy to say that it does occur. So when there is hæmorrhage, there is no proof that that portion of blood which exudes, is more vitiated than the rest; and it is to be remembered, that it is only a *part* of the blood which escapes. All these changes of the fluids are, most probably, owing to the solids in the first instance. A morbid cause makes a peculiar impression upon the body, as a living system; it impresses the solids; and, by the operation of the solids, the fluids are secreted in a vicious manner, and of a depraved quality. It is probable that the vitiated state of the fluids, arises from the solids not having manufactured them properly; unless, indeed, a quantity of improper materials be supplied to the body; which the body, without any fault of its own, can make nothing of. In that case, the solids certainly are not in fault. They do their best; but they are obliged to manufacture (if I may so speak) a bad article, because they have bad materials. With this exception, I imagine that the fluids must become depraved through the solids; though of course they, in their turn, must exert an evil influence. Again: it is a fact that fever will continually cease, without any discharge;—without sweating, or diarrhœa, or loss of blood at all. It is most probable that, when these things take place, they are the result of the healthy change altogether. In fever, we may get a patient to sweat profusely; but perhaps he will not be any better for it. If, however, we lessen his disease, then probably he sweats. His improvement is not the result of the sweating; but we have brought him into an improved condition; and sweating then takes place spontaneously, as it were. Frequently, in fever, diarrhœa occurs without any relief; we stop it, and the patient is all the better for the suppression. The critical discharge, too, when it does occur, and when a patient is improved at the same time, is for the most part too small to explain the improvement. It would seem that the discharge is rather the *consequence* of the improvement than otherwise. The improvement occurs; and the discharge takes place, almost as a matter of course.

Again: it is to be remembered that the fluids do, in fact, undergo a peculiar change. As the disease advances and the debility goes on, the saline matters of the blood are more or less deficient; and the blood becomes more and more watery. It is said by a friend of mine, Dr. Stevens, that we can remedy this state, not by the remedies for inflammation, but by supplying the deficient substances in the blood. Of that, however, I shall speak presently.

*Spasm; Debility.*—Some authors have asserted, that fever is owing to a spasm of all the small vessels. I presume that there is spasm in fever;—that so long as the solids do not secrete, we must suppose that the vessels are closed, so that the fluids cannot escape; but though there be spasm at a certain period, when the secretions are all deficient,—though we allow that this is *one* striking circumstance, yet there is no reason to imagine that it causes *all* the symptoms. Other persons have assumed, that debility is the cause of fever; but people are weak enough, every day, without having fever; and if debility be *one* of the circumstances of the disease, yet there is no proof that debility is the *cause* of the symptoms.

*Inflammation.*—Many think that inflammation will explain every thing;—not only changes of structure (upon the absurdity of which supposition I have already

dwelt;\*) but every thing else that occurs morbidly to the body. It certainly is the first circumstance that takes place in many changes; and it *accompanies* many changes, but there is no proof that this is *always* the case. Syphilis, for instance, is an inflammatory disease. The first thing that occurs, is a pustule, or a mere inflammatory speck, followed by ulceration; and the next occurrence is an inflamed gland; and then, when other symptoms arise, they are more or less inflammatory. If blood be drawn during the secondary symptoms, it is often found buffed; and we have inflammation in different parts of the body. Syphilis, however, is something more than inflammation. So it is with cancer; so it is with encephaloid disease, and melanosis; and so, I think, it is with fever. Inflammation forms a part of a large number of cases; but it is not sufficient to explain them; otherwise a mere case of phrenitis would be, in every instance, a case of fever; and every case of inflammation of the stomach, or of inflammation of the bowels, would, if there were a certain degree of excitement, be a mere case of fever; which undoubtedly is not the case. Another argument against fever being mere inflammation is, that it is frequently cut short, in a very early stage, by an emetic; or by cold affusion;—not ablution, but affusion. Now this could not be done, if the disease were nothing more than local inflammation; or if it were inflammation at all. Again; inflammation will not explain the difference between typhus-fever and plague; which, though different diseases, are nevertheless in many respects analogous. Inflammation will not explain scarlet-fever; nor will it explain measles; yet they are both inflammatory diseases. The symptoms are decidedly those of inflammation, in a great number of cases; but there is something more than that. The system is in a peculiar state; and inflammation is merely one of the circumstances. Some have imagined that inflammation produces even intermittent fever; but we have no explanation of it; and this is a mere assumption. Any thing may be said in physic; but any thing may not be right.

That the body, in fever, is frequently in an inflammatory state throughout, there can be no doubt at all; neither can there be a doubt that in fever there is continually local inflammation; but there certainly is something more than all this in fever. There is a peculiar feeling of debility; a peculiar aspect of the countenance; generally pains, at first, in the loins; a tremulous tongue, and universal disturbance;—such as cannot arise from any simple local inflammation in any one part. Many of these symptoms are certainly not referrible to an inflammatory state; and if the disease be contagious, then this shows that there is something more than mere inflammation. The local inflammation which occurs, is by no means proportionate to the violence of the fever. There is frequently violent fever; and, although local inflammation be present, yet the latter is not at all in proportion to the former. In some instances, death takes place at the very first, without any inflammatory state being produced;—just as in small-pox (which unquestionably is a contagious disease) the patient sometimes dies, before any inflammation becomes visible;—death taking place merely from the depressed state of the system. Frequently we find the disease running on, and proving fatal, without any decided marks of inflammation at all;—without any thing that bears a proportion to the general sinking of the system. Besides, there are peculiar symptoms in fever, which mere inflammation would not at all explain; such as the particular look of the face, the tremulous tongue, and the extreme feeling of debility of the body. Mere inflammation, whether general or local, although it is a circumstance that frequently occurs in fever, is nevertheless quite insufficient to explain the whole of the symptoms. It is *one* fact in the disease; but not the *whole* of the facts; nor is it a fact from which any one can prove, that the other set of symptoms arises.

*The Nervous System.*—With respect to those who consider that it is neither situated in the fluids nor the solids generally, but in some one part of the body, I may mention that Hoffmann thought it was a disease of the nervous system. The nervous system certainly is affected, and so likewise are the secretory organs; and

\* See Pages 176 and 177.

therefore others have just as much right to say that it is a disease of the secreting system, as Hoffmann had to ascribe it to the nervous system.

*The Capillaries.*—Dr. Wilson Philip supposes it to be an affection of the capillaries throughout the body; but then there is a peculiar affection of the nervous system in general; and there is particularly a disturbance of the abdominal organs.

*The Brain and Abdomen.*—Some have fixed upon inflammation of the brain. Former writers have done that; and a modern physician, in London, has done the same;—he considers it a mere inflammation of the brain.<sup>a</sup> Others, again, in Paris, fix upon the abdomen. Broussais, for instance, considers it to be inflammation of the stomach and bowels;—what he calls “gastro-enteritis.”<sup>b</sup> Some patronize one organ, some another.

It is true we may find morbid appearances there; but it is also true that we may open cases of fever, and find the intestines sound; or, at least, with no such appearances as will explain the symptoms of fever. I have, over and over again, inspected cases, in which there was no inflammation of the intestines; and which, if the fact had not been told, would not have been known to be cases of fever. There might sometimes have been a little more redness than usual, in this or that intestine; or if even there was any thing morbid, still it was insufficient to account for the general symptoms of fever. The symptoms observed during life, frequently depend upon local affection; but frequently there is no disease existing in any particular part. Andral<sup>c</sup> says, that of thirty-eight cases of fever which he examined, only eleven presented marks of gastritis sufficient to have influenced the symptoms during life. Thirty out of the thirty-eight showed some sort of intestinal affection; but only fourteen of these (that is, fourteen out of thirty-eight) exhibited such a morbid affection of the intestines, as could explain any of the symptoms during life. He also says, that the changes which are seen in the nervous system, are comparatively rare and slight. I do not think that fever is to be explained by Morbid Anatomy. Many of its symptoms, and many of the occurrences which take place, may be thus explained. When there is phrenitis, we usually have the *marks* of phrenitis; when there is bronchitis, we usually have *marks* of bronchitis; when there is diarrhœa, we expect to find ulceration of the intestines;—but frequently these symptoms are but slightly or not at all apparent; and after death there are no such marks as will explain fever; although there may be enough to explain the local symptoms that have occurred. Continually is it observed, in fever, that the head is but slightly affected after the first few days; and that the abdomen is scarcely affected at all.

Now I believe, as I just now mentioned, that the head is frequently in a state of inflammation, and so is the abdomen; but occasionally the head is far more affected than the abdomen; and in other cases the abdomen is more affected than the head. I stated that the local inflammation frequently bore no proportion to the general symptoms of fever; and sometimes we have violent local inflammation, without any corresponding symptoms of fever. The same is the case with regard to the relative affection of the head and abdomen. Sometimes the head is more affected than the abdomen, and *vice versa*;—they do not bear any proportion to each other. If we assume local inflammation to be the cause, and if we observe the phenomena of many cases, we have no more right to settle the affection in the head, than we have in the abdomen.

All these I consider to be mere circumstances constituting a general collection of

<sup>a</sup> See “An Inquiry into the Seat and Nature of Fever; by Henry Clutterbuck, M. D.”

<sup>b</sup> “Histoire des Phlegmasies, ou Inflammations Chroniques. Par F. J. Broussais.” A Translation of this work has been published at Philadelphia.

<sup>c</sup> Andral, I think, is one of the soundest writers on Medicine. He appears to have no theories; but to look out for facts, and to make the most correct and philosophical use of them. I have found all that he has said, in his Clinical Reports (“Clinique Medicale”) to be confirmed; and though it was not till lately that I read his book, yet I was delighted to find the coincidence in our facts and inferences.

truths; but I do not see any reason to suppose that there is disease of one part, more than of another.<sup>a</sup>

Although I deem it necessary to make these remarks, yet I shall not attempt to state what I believe fever to be. I really do not know what it is; and I think it is always a great blessing to know one's ignorance. It is well not to fancy ourselves acquainted with things with which we are not; because if we fancy we are, we sit down contented, and never think of examining the subject further. An excellent observation of this kind is to be found in Voltaire's "Philosophical Dictionary," under the word "*idea*." A person is there represented as lamenting, that he has got so many ideas;—that his cerebral matter is full of ideas; but that he is perfectly miserable, because he cannot tell what an idea is. He fancies it is this, that, and the other; he indulges first in one hypothesis, and then in another; and says it is a shocking thing not to know what it really is. His friend tells him, that—"Il est bien triste d'avoir tant d'idées, et de ne savoir pas au juste la nature des idées." "Je l'avoue," replies the other; "mais il est bien plus triste, et beaucoup plus sot, de croire savoir ce qu'on ne sait pas."<sup>c</sup>—I imagine that we do not know the peculiar state of the system in typhus-fever; any more than in measles, or in hooping-cough. A peculiar cause has operated upon the body; and a peculiar state has been thereby induced; but we can observe only its *effects*.

## SECTION VI.—TREATMENT.

*Ventilation and Cleanliness.*—Notwithstanding this uncertainty, however, the *treatment* of fever is in the highest degree rational, and in the highest degree successful. We must aim, in the first place, at having free ventilation, and the most perfect cleanliness:—plenty of washing, plenty of clean linen, and plenty of fresh air. With fresh air and fresh water, we may go on very well; but if there be any smell, which ventilation and washing will not remove, the chlorides are excellent things. They should be sprinkled upon the bed, or upon the floor; and disposed in saucers, or in rags dipped in the solutions, and hung on the backs of chairs about the room. A solution of chloride of lime ought to be put into the utensils which the patient employs; that no unpleasant smell,—no contamination may arise in the room. When a patient is first seen, if he be dirty, it is right (before prescribing any thing else) to prescribe soap and water. Before any thing else is done, I would always have a patient got perfectly clean. When he is well cleansed, with soap and water, all over his body; and especially his lower half, and his lower extremities,—a portion which is sometimes exceedingly filthy,—you should have him well washed with plain water, several times a day. Soap is no longer required; but sponging, several times a day, is always of importance. I believe it is always safe, in fever, to wash a patient with warm water; but if he say that he is hot, or if (on placing the hand upon him) we feel that he is hot, we may employ cold water.

<sup>a</sup> The following table, selected from the Journals of the London Fever Hospital, shows the comparative frequency of the several local lesions, which arise during the progress of fever, as observed in that institution; and offer strong confirmation of the correctness of Dr. Elliotson's opinion:—

I. Cases in which the fever was not apparently complicated with local inflammation in any organ	-	-	-	-	-	-	-	-	-	163
II. Cases complicated with cerebral affection	-	-	-	-	-	-	-	-	-	114

<sup>b</sup> "It is very sad to have so many ideas, and not to know accurately the *nature* of ideas."  
<sup>c</sup> "I confess it; but it is much more sad, and much more foolish, to think we know that which we know not."

*Cold or Tepid Affusion.*—If the temperature of the patient be steadily above  $98^{\circ}$  (as ascertained by a thermometer placed under the tongue, or in the axilla); if there be no pulmonic affection, no general profuse sweating, and the patient himself does not say that he is chilly,—we may take him out of bed, and throw a pail of cold water upon him. This is “cold affusion;” and may be repeated. The patient must be dried, and put to bed; and, as soon as he grows hot again, the same measures may be adopted. This plan makes him exceedingly comfortable. Frequently it induces perspiration; and frequently it sends him to sleep; but even if it fail of this, it nevertheless makes him very comfortable, and sometimes cuts short the fever. Upon this subject, Dr. Currie’s “Medical Reports”<sup>a</sup> should be perused. But in general I do not find the heat steadily above  $98^{\circ}$ ;—I do not find patients free from a certain degree of chilliness; and I therefore content myself with tepid or cold ablution. I have never had occasion for affusion; but it is always safe, under the restrictions I have laid down. The cold bath is too chilling a thing;—it would strike too suddenly. But when it would not be safe to take a patient out of bed, and throw cold water upon him, we may always have recourse to ablution, either cold or tepid. I always make it a rule to consult the patient’s feelings on this point; and if I think he cannot bear much cold, I have him stripped, and sponged all over with tepid water; and between the intervals of this treatment, basins of cold water should be brought to the bed-side, and he should be allowed to put his hands into them as often as he thinks proper; and his face, too, should be continually washed. If there be any pulmonary affection, or if the patient say that he is chilly from the ablution, then we should use it tepid; for I need not say that tepid ablution is a great source of relief, and that it cools the patient considerably. It does not produce the impression that is made by cold water; but a great degree of evaporation takes place; and it extracts a certain portion of the patient’s temperature. When it is applied, its temperature need not be  $98^{\circ}$ . From  $80^{\circ}$  to  $90^{\circ}$  is sufficient; and it cools the patient by its subsequent evaporation.

To co-operate with this treatment, the patient should have but few clothes upon him; and the windows and doors should be opened;—so that he may have, not only a free ventilation, but at the same time a cool temperature. The doors and windows should be wide open; unless the patient feel chilly, or the draught seem too strong for him. As the disease lasts longer, we must apply cold less. There is not the same power of generating heat;—the patient is not so hot as before; and therefore the application of cold is less advisable; and we find it necessary to use *tepid* ablution, where previously we used *cold*. Indeed, as the disease advances, and the patient is getting better, there is little occasion for much abstraction of temperature. Ablution, whether warm or cold, is less and less frequently wanted; and a low temperature is less and less required. But while, in general, ablution is employed for the purpose of *cooling*, it should still be partially employed for the purpose of *cleansing*. The hands, the feet, and the head, ought to be looked after.

*Temperature of the Apartment.*—With regard to the temperature of the room, the same rule is to be observed as at the beginning; that is to say, the patient’s feelings ought to be consulted. If he be delirious, of course we must not attend to him, but judge for ourselves; but if he be not delirious, and say that the temperature of the room is unpleasantly cold, then we ought not so freely to diminish it.

*Emetics.*—While thus attending to the surface of the body, we likewise have to attend to the inner surface,—to the alimentary canal. It is a good practice, in the beginning, to give an emetic; but if, on making pressure, we find tenderness of the epigastrium, or any part of the abdomen, I would not have recourse to any such measure. If, indeed, there should be a violent determination of blood to the head, I do not know that I should have recourse to it then. Frequently, however, in the beginning of fever, it is an excellent practice to give an emetic;—for instance, a grain of tartar-emetic, with a scruple of ipecacuanha; but I should never think of

<sup>a</sup> “Medical Reports on the Effects of Water, Cold and Warm, as a Remedy in Fever, and Febrile Diseases. By James Currie, M. D.”

giving it, without first ascertaining whether the abdomen, on pressure, is tender or not. Sydenham gives very good advice on this point. He advises us to premise bleeding, before we exhibit the emetic. This practice is not always necessary; but if the pulse were full, and there were great signs of a determination of blood to the head, I would bleed first.

*Purgatives.*—But whether we give emetics or not, there is no doubt of the propriety, in every case of fever, of seeing that the bowels are regularly opened;—that no filth collects in them, any more than on the surface. They should be freely opened, for the most part, every day;—at least at the *beginning* of fever. If they be confined, one of the best medicines is a large dose of calomel. The quantity must vary from two to five, ten, fifteen, or twenty grains, according to circumstances; but, in most cases, five grains of calomel, followed by castor-oil every two hours, will answer every purpose. Now and then we have obstinate constipation. A patient may not have had a good stool for many days; and then we may give ten grains or a scruple of calomel, and follow it up by castor-oil; but it would be wrong to give a dose of that description, if there were every probability that a few grains would answer the purpose. Nothing is better than to follow it up with castor-oil; but, at the same time, we are likely to accelerate its operation, by giving a common injection. This, however, is not to be done if the bowels be sufficiently open of themselves;—if they be open once a day. Sometimes it will happen that they are *too* open;—that there is the *opposite* state,—that of excitement; and then, of course, purgatives would be highly improper. The purgative plan, when necessary, is to be put in practice at the *onset*; but, with regard to ablutio, I would (as I have stated<sup>a</sup>) continue it during the *progress* of the disease. Calomel certainly does clear out the intestines better than any thing else; although it usually requires another purgative to set it off. But although we clear out the bowels well in the first instance, by means of calomel, we nevertheless often find it a good practice to go on with smaller doses of that medicine, or other preparations of mercury, during the course of the disease. This will generally prove quite sufficient to keep the bowels open, without any thing in addition; but if from two to five grains, exhibited every eight, six, or four hours, do not effect that object, we must accelerate the action of the mercury, from time to time, either by an injection, or by a moderate dose of castor-oil. Senna and salts are given by some practitioners; but, upon the whole, I think castor-oil is best. Indeed, if the stomach or the intestines be irritable, we ought not to do more than give an injection. Accumulation and torpidity, however, do not always exist; for sometimes we have diarrhœa, and the whole of the abdomen is tender; and of course purgatives, in such a state, are likely to do more harm than good. It is right, before debility arises, to have one, two, or three stools a day; but, if they take place without medicine, and be of a watery character, it is necessary to restrain them, lest the patient should sink. As a general rule, where there is no irritation of the bowels, or much real debility, we ought to make a point of procuring two or three stools a day. There is no rule for the dose of calomel; but, if given in small and repeated doses, it generally keeps the bowels in an open state;—sometimes, indeed, more open than we wish.

The use of purgatives in fever is very great; but, undoubtedly, it has been exaggerated by certain writers.<sup>b</sup> Some books would lead us to conclude, that we have only to turn the patient inside out, in order to cure him; but I am quite certain that such is not the case. There is sometimes found a great disposition to diarrhœa, which it is absolutely necessary to restrain; but no one can dispense the propriety of removing all filth, once or twice a day, from the alimentary canal. Costiveness ought never to be allowed; for it causes the tongue to be brown and dry; and, except in the last stage of fever, where there is frightful debility, there ought to be one stool in the twenty-four hours.

*Blood-Letting.*—The treatment already mentioned, will enable us, in the greater

<sup>a</sup> See Page 321.

<sup>b</sup> See Dr. Hamilton's celebrated work, entitled "Observations on the Utility and Administration of Purgative Medicines in Several Diseases."

number of instances, to get rid of fever;—such instances, at least, as I see. In other cases, however, it is necessary to be more active. It is necessary to take away blood; and it may be done either at the arm, or by what we call “*local means*.” Venesection is certainly not required for mere generally increased action. If no organ in particular be suffering;—if we cannot discover great excitement of any one organ;—if there be mere general excitement of the system, I do not believe that venesection is required. However, if the epidemic be of such a character, that inflammation is sure to come on, it is as well to bleed in the arm; in order to prevent such inflammation, when it does come on, from being so violent as it otherwise would. But, as a general rule, in the fevers that I see in London, venesection is not demanded in one case out of thirty or forty. It would be wrong for me to speak of what people see in other places; because fevers differ in different situations. In the country, where people are strong and plethoric, and in hot countries where the excitement is sometimes exceedingly great,—the congestion within the head, chest, or abdomen, vary considerable,—the lancet is the “sheet anchor;” whereas, in the majority of continued fevers which I see, venesection is certainly not necessary; and I am sure that those who employ it extensively in this disease, if they do not destroy their patients, yet protract their cases. However, it is of great importance to employ *local* bleeding; and, except in hot countries, I think every good may be obtained from it, in the majority of cases, without that shock which *general* bleeding produces; and which is very desirable in mere inflammation. In *fever*, this shock is not demanded. In comparatively *mild* fevers, it would make the disease severe; and in those of an *asthenic* character, it would knock the patient down.

*Blisters*.—After a proper detraction of blood, or in a case where the loss of blood is not advisable, blisters (applied to the nape of the neck, or to the forehead, or behind the ears) are very useful. A blister applied to the summit of the head, is generally a painful thing; and I would not have recourse to it, except as a last measure. Before the inflammatory state has much subsided, and before there is really more of irritation than of inflammation, the application of blisters would of course be doubtful almost anywhere; but particularly at the top of the head. The hazard, however, would certainly be far less, if they were applied to the nape of the neck, to the occiput, or to the forehead. Leeches must be repeated at intervals;—as long as the local symptoms seem to demand them, on the one hand; and the strength of the patient will bear them, on the other. When, however, notwithstanding local inflammation or irritation, we do not wish to apply even leeches or blisters, mustard-poultices are particularly useful. When applied over the epigastrium, they will stop vomiting. They are very serviceable over the abdomen; and by many persons they are employed at last, or even in an early stage, to the feet; with the view of exciting distant irritation.

*Small Doses of Mercury*.—In many of these fevers, it is of the greatest use to give mercury; especially if there be a degree of inflammation, and great foulness of the tongue. If given in small, but repeated doses, it will answer the purposes I have already mentioned.\* It not only purges the patient, but (by degrees) causes the tongue and the interior of the mouth to become moist; and when that is effected, the patient is almost sure to be better. It is necessary to remember, that it should not take the place of local bleeding. It will increase the good effect of detraction of blood; and where that is not required, it will do alone; but where that is necessary, mercury must not take its place. It must be used as an auxiliary to bleeding; and not as a substitute for it. Over and over again, in treating patients, I have omitted the mercury; and have seen the tongue grow darker and fouler; and then, upon having recourse to it again, I have seen the mouth resume its moisture, and the tongue become less foul. I have made the observation too often to doubt its accuracy. It is true there are many cases of fever, that will do without mercury. I only say that, in the mass of cases where mercury is given,

\* See Page 322.

the success is greater than when it is omitted. We cannot draw any argument from a single case; it is only from a series of cases, treated in a particular way, that we can arrive at any legitimate deductions; and as far as I have seen, the moment the mouth becomes moist,—provided proper detraction of blood be instituted, and all other suitable means,—the local symptoms of inflammation generally decline; and patients recover more quickly than they otherwise would; and many recover who (in all probability) would not, unless that practice were resorted to. Still (I must repeat) a great number of cases of fever will do well without it; but, where the symptoms are severe, we find it a most useful medicine. We should not aim at any violent affection of the month; and, if that should occur, the medicine must be omitted till the symptoms remit; but we should feel the patient's gums every day, to ascertain whether the mercurial effect is kept up. There can be no doubt that mercury will sometimes take effect, not in consequence of having cured the disease, but by the disease becoming better (through nature and the general means employed), and the mercury being no longer resisted. The proof of mercury doing good, consists in this fact;—that if it be given quickly, so as to get the mouth sore, the sooner that object is effected, the sooner in general is the patient improved.

Calomel, however, is frequently too active for the intestines; blue-pill, or Hydrargyrum cum Cretâ, answers better. After a time, even these will purge; so that it is necessary, along with them, to exhibit chalk-mixture, or an infusion of catechu. It is well to give the infusion of catechu or kino, for it will enable the patient to bear the mercury; and we frequently find that Hydrargyrum cum Cretâ is the only mercurial preparation that can be borne. Mercury, if pushed too far, increases the mischief;—it induces great irritation of the alimentary canal. A remedy, how excellent soever, requires (of course) to be *properly* used. Small doses of opium, I need not say, will tend to check the diarrhœa; and frequently there will be no objection to five drops of the tincture, three or four times a day.

*Antimony.*—As to antimony, I do not think it an appropriate medicine; for it irritates the stomach;—a circumstance which is not wanted in fever. There is so frequently also a disposition to sickness, that it is very likely to excite vomiting. If we give mercury at the same time, the antimony has a great tendency to counteract its effect. It may cause the mercury to be rejected; and, I confess, I have never seen any material good done by it. In cases of decided inflammation, it would be a good remedy, pushed to a large quantity; but when the case is attended with great irritation of the alimentary canal, (as many attacks of fever are,) and the patient has but little strength, I am sure that it is better not to give antimony;—lest we make the patient's stomach so irritable, that it will not bear food, or any thing else. It is only where there are very decided marks of inflammation, that it might be given; and even then I should much prefer mercury. As to its sudorific effects, I have given antimonial wine in very large doses, without producing sweating. The best mode to ensure sweating in fever, is to clear out the bowels, to reduce the temperature of the surface, and to take away blood locally or generally, accordingly as it may be required. I have seen patients lying in a carpeted room; with the windows shut, plenty of bed-clothes on, and perhaps a fire in the room into the bargain;—and all this, I have been told, was to excite “a gentle diaphoresis!” The diaphoresis, however, never made its appearance; but on opening the windows, putting out the fire, removing the bed-clothes, taking up the carpet, purging the patient well, and removing any local inflammation that was present, it has come on immediately. The idea of a few grains of antimonial powder, or a fraction of a grain of tartar-emetic, once or twice a day, being important in fever, appears to me quite absurd. With the treatment I have mentioned, nothing else will be required, till great prostration of strength sets in.

*Treatment of Local Complications.*—It is necessary, in every case of fever, to be constantly on the look-out for local inflammation;—every day to ascertain what is the state of the head, the chest, and the abdomen. We should always ask if the patient complains of headache. Look at his eyes; and see whether they

are red or not. Ascertain if his pulse is full; and inquire whether there is any throbbing of the head. So, with respect to the chest, we should observe whether there is difficulty of breathing; and if there be, it is well to apply the stethoscope, and ascertain what rattling there is. The abdomen ought to be carefully felt every day; in order to ascertain whether the stomach, intestines, liver, peritonæum, or other parts, be inflamed. When we find a sufficient degree of inflammatory disturbance of these parts, then it is right to take away blood locally. If the head be affected, then we should cup at the back of that organ; or apply leeches to the forehead, temples, or behind the ears; but if it be the abdomen which is affected, it is always better to employ leeches. If the pain be situated at the front of the head, it is better to employ leeches there. I mentioned,\* when speaking of inflammation, that the effect of leeches or cupping is often very local. I have seen parts where they were applied, relieved; while others, in the neighbourhood, remained as painful as before. At whatever part of the head the pain is felt, there we should direct our means of treatment. If there be delirium, and this delirium be accompanied by pain and heat of the head, or throbbing; or if the eyes be red; or if there be great vivacity, like incipient delirium of an active kind; we ought always to shave the head, then apply a cold wash, or employ a bladder of ice (which is one of the best things), and put plenty of leeches on, or employ cupping at the occiput. If there be vomiting, or tenderness at the epigastrium without it, we should apply leeches, which are the best for it; for, when there is tenderness or vomiting, it generally arises from inflammation of the mucous membrane; and leeches will remove it, by removing the causes of inflammation. So, with regard to the abdomen at large, when that is tender, there is generally more or less diarrhœa; the intestines are acting too violently; and leeches, freely applied, are the best mode of restraining it. After they have been used, apply a blister; but always remember, that a blister will not take the place of local bleeding, if the inflammation be considerable. If there be local inflammation, we frequently find that the application of leeches will remove it; and after it has greatly subsided, slight inflammation, or mere irritation, may be left; and a blister may be of the greatest use. We shall see, when I come to speak of diarrhœa, that leeches and blisters are frequently the best remedy for it.

*Cooling Drinks.*—All cool drinks are proper; and a saline draught is as good as any thing which can be given for a drink. People will frequently take half a pint to a pint a day. It is always to be remembered, however, that all acid matters, and even a saline draught, have a tendency to increase any irritation that may be present in the bowels; and diarrhœa is frequently kept up, by a saline draught being continued. But if there be no purging,—if the alimentary canal be tranquil, acidulated drinks are very useful. Upon the whole, however, a downright cool drink,—plenty of cold water, is one of the best things that can be given.

*Treatment of convalescence.*—As the symptoms all decline, all the remedies must be diminished, both as to force and to frequency; and there may be less abstinence practised. Nourishment may be gradually given; and one of the best articles, after slops are done with, is milk. It is very wrong to continue starving a patient after fever is gone; for when the fever is over, the appetite becomes remarkably keen;—keen in a degree that is never witnessed after any other acute disease. Patients, when the fever is over, are sure to say they are very, *very* hungry. Other patients will ask for full diet; but patients after fever ask with great earnestness. They seem to have a craving which impels them to ask it;—whether they think it will offend or not. Patients are more emaciated after fever, than after any other acute disease. Even when no evacuations have been practised by the medical attendant, and when the disease itself has not been attended by any great evacuations, there will still be a degree of emaciation, which I think is not witnessed after any other disease; and when the fever is over, and there is so great a craving for food, it would be contrary to common sense to with-

\* See Page 123.

hold it. It seems to be a real call of nature;—it seems that food is absolutely demanded. I always make a point of giving them light animal food;—not pork or veal, or artificial trash; but plain mutton, and good fresh beef; and carefully watching the effect.

*Treatment in Extreme Debility.*—Suppose, however, that the disease does not run on in this mild form; or that the inflammation does not become subdued, as in any inflammatory disease; but that signs of great debility come on; we must then have recourse, even in the midst of fever, to good support. Milk should be given, in as great abundance as the patient can take it; and, I think, strong beef-tea. Some imagine that, the digestive process being suspended in fever, animal broths cannot be digested; but, however, that may be, I know that persons who take strong beef-tea, frequently do admirably well. By “strong beef-tea,” I mean a pound of meat, chopped extremely small, and boiled in a quart of water, until the latter is reduced to a pint. Some persons will take two or three pints of it in a day; while some require only one pint;—and we find them considerably nourished by it. Many persons cannot take milk; but, where it can be borne, it is excellent nourishment. Arrow-root, sago, and rice, may be taken with the milk. I believe that, occasionally, we must give more nourishment than can be introduced by the mouth; and when there is extreme prostration, it is useful to give strong clysters of beef-tea, in which an egg may be diffused. I have seen them given to a patient every four hours; apparently with the result of getting him through the disease. If the clysters be discharged again, and not retained sufficiently long to be beneficial, it is useful to put into each of the injections a drachm, or two drachms, of powdered catechu.

*Wine.*—More than all this, however, is sometimes required; and we must give a patient wine. If we give wine, as a *general* remedy for fever, I am certain that we shall kill one half of our patients; but if we give it in the latter stages of the affection; or if, from the first, the disease be attended with great debility, we shall frequently do much good by its exhibition. It is often indispensably necessary, but not (so far as I have seen) at the *beginning* of fever. A great number of cases do well without it altogether; but I have seen cases, over and over again, where a glass or two of wine has stopped vomiting or diarrhœa. It is where there is extreme debility,—where there is *irritation* rather than *inflammation*; and where we find that the pulse is feeble,—almost fluttering; and the aspect of the patient indicates that he is sinking;—it is here that I have found it beneficial. I have always been accustomed to quote Sir John Pringle on the exhibition of wine; because I think that his directions, both as to the quantity required, and the time at which it is to be given, are the best which have been written. He says, “In our malignant fever,” (he was physician to the army,) “when the pulse sunk, it always became very frequent” (that is generally observed); “and in proportion as it rose with the wine, it turned slower. I have also had experience of the good effects of wine, when the tongue has been both foul and dry.” Here is an illustration of the propriety of not attending to one symptom, but to the whole. A dry and foul tongue frequently indicates inflammation; but if no inflammation be present, but (on the contrary) great prostration of strength, with a fluttering pulse, an anxious countenance, and inability of the patient to move himself,—then we need not fear foulness and dryness of the tongue; but may exhibit wine. “When wine is given,” Sir John Pringle says, “in proportion as the patient grows stronger, the pulse becomes slower. Wine, in health, will *accelerate* the pulse; but when a person is weak, and the pulse is quick in proportion to the weakness, and when this state does not arise from inflammation, but downright exhaustion, wine, instead of *quickening* the pulse, makes it *slower*. The surest indication for wine,” continues Sir John, “is taken from the long continuance of the disease; the languor, and dejection of strength; and the slowness and faintness of the voice; but we can never be absolutely certain of its effects till we try it.” This is also a point carefully to be attended to. We constantly meet with cases, where there is a doubt as to the proper mode of treatment to be adopted. This occurs to me every day; and will

occur as long as I live. We are not certain whether the time has arrived, at which to treat the case as inflammatory or not; and we are often made unhappy by this circumstance. Whenever a suspicion of this sort arises, it is best to combine both modes of treatment;—to lessen any excitement; and to begin stimulating and tonic remedies, with great caution. Whichever is found to do good, must be increased; and, in fact, substituted for the other plan. “I have seen,” Sir John Pringle says, “in cases of this kind, strange instances of the power of instinct; for when wine was to do good, the sick swallowed it greedily, and asked for more; but when it was to heat them, or raise the delirium, they showed an indifference, or even an aversion to it.” It is of the greatest importance, in fever, to attend to the wishes of the patient,—provided he be not delirious; for then he will talk at random. But if he be not delirious, or only partially so;—if he be sufficiently collected to know his own feelings, and to give a clear account of those feelings, they should, in general, be attended to. “Sometimes,” he then continues, “the physician can have no better measure for the quantity requisite, than the appetite of his patient.”

*Quantity of Wine Necessary.*—Half a pint of wine is sometimes required in twenty-four hours;—one glass being given at a time. Generally a pint is the utmost that is requisite; though I have given a bottle with advantage. It is best not to give Rhenish wines, or thin claret, or any acidulated wine; for, if diarrhœa be present, it will increase the irritation of the alimentary canal. It is also best not to give sweet wines; for they are apt to ferment and become acid in the stomach. Sherry, Madeira, and Port, are the best that can be employed. If there be no irritation of the alimentary canal, but a torpid state of it, acidulous wines may sometimes, perhaps, be admissible. If the patient desire porter, or has been accustomed to it, that is very good; but we should not give a pint of porter at once. A wine-glass or two may be given every few hours; or perhaps only once in the twenty-four hours. Because a person desires porter, we are not necessarily to give a pint in the twenty-four hours. When there is mild delirium (not “delirium ferox,” but a “muttering delirium”), or when the pulse is rapid and weak, and when extreme debility has come on, then it is right to resort to this treatment; for it will frequently stop the delirium, or (at any rate) check it. But if we go on with it after it has stopped the delirium, it will frequently bring it back;—so that the patient is worse than he was before.

*Other Stimulants.*—In this state of debility, many give ammonia and ether; but I cannot help thinking that wine, or good malt-liquor, is the best article that can be exhibited; unless the malt-liquor bring on diarrhœa. It is much better to give those stimulants which most people like, than to give ammonia or ether. The former are *natural* stimulants; and are much more grateful to the patient. Care must be taken, with all these things, not to overload the stomach. The moment you find the head affected by them, or the stomach overloaded, it may be necessary to give an emetic. For the same reasons that I have already stated, I should also prefer giving wine, to giving what are called “*vegetable* stimuli;”—such as serpentaria. It is true I know nothing about them. I dare say they are good; but I have always been able to do without them.

*Tonics.*—As to tonics, by far the best is quina. If we judge it right to attempt supporting the patient by means of quina, it should be given, in doses of three or four grains, every three or four hours. I certainly fancy that I have saved patients in the last stage, when there has been no longer room for giving mercury, by supporting them well with good nourishment and wine, and by giving sulphate of quina in considerable doses. But it must be remembered that, in giving sulphate of quina as a tonic, it may do harm by purging; and therefore we should be on our guard against this, by administering astringents at the same time. I frequently accompany it by catechu; and then the irritation is generally put a stop to.

*Saline Treatment.*—Dr. Stevens says that, in this state of debility, he has seen great benefit arise,—far greater benefit than from any thing else,—from very small and repeated doses of the carbonate of soda, nitre, muriate of soda, or chlorate of potass; which supply the deficiency of saline particles in the blood. He has a

vast collection of testimonies in favour of the saline treatment in yellow-fever; where, after a certain period, ordinary treatment generally does more harm than good. In all such fevers, he contends that, in the first instance, it is the best practice to bleed the patient and give mercury; but, after a certain period has arrived, the blood falls into the condition I formerly stated;<sup>a</sup> and that condition is made worse by mercury; and, of course, by bleeding; but he says it is admirably remedied by small doses of neutral salts, particularly those I have mentioned. Twenty or thirty grains are given every three or four hours; except of the chlorate of potass; of which about a third of that quantity is a dose. It appears that those who have adopted this plan, in the West Indies, have had the greatest success. He informed me that, in yellow-fever, many had agreed that they did their patients altogether more harm than good by treatment; and that those succeeded best who gave nothing but saline draughts, in large quantity. Neutral salts are now given, in the large doses I have stated, and with the very best effect. By adding neutral salts to blood, however black it may be, we make it of the brightest scarlet; but if we add acids or alkalies to red blood, we make it black.

*Opium.*—In the last stage of fever, some give opium in small doses, for the purpose of keeping up excitement. Dr. Wall, of Oxford, and Sir John Pringle did so; but others give a dose once in the twenty-four hours, for the purpose of tranquilizing the system. I have no great experience of it as a stimulant; but I know that, when a patient has long laboured under fever, it is quite safe to give him a dose of this kind, in order to procure him a good night's rest. I suspect that wine is a better stimulant than opium; although opium is certainly exceedingly useful in the latter stages of the complaint. Some highly praise musk. I need not say that morphia is sometimes greatly adulterated. It is said that opium is not always of a certain strength, and that morphia is; but, from being adulterated, morphia is of the same uncertain strength as opium. Opium is particularly useful in procuring sleep; and in putting a stop to vomiting and purging. The muriate of morphia is an admirable form of opium, if not the best.

*Concluding Remarks.*—The treatment of fever, therefore, consists in subduing inflammation, on the one hand; or in supporting the strength, on the other; and we must always carefully look out for local symptoms, and check them. The vomiting is frequently urgent, and very distressing to the patient; and although effervescing draughts will sometimes stop it, as will also hydrocyanic acid, yet if there be inflammation present, it is not in the nature of these remedies to arrest it; and we must then employ leeches, blisters, or sinapisms. So with regard to purging, opium will frequently put an end to it, and so will all astringents; but, as I have before said,<sup>b</sup> it is best not to give astringents if there be inflammation present. Leeches and blisters will then effectually subdue it, when nothing else will. If the fæces be exceedingly fetid, it is a very useful plan to give yeast, either by the mouth, or in the way of injection. An injection of yeast will frequently very much correct the offensive odour. Some give it in porter. The injection of the chlorides would, I fancy, be useful; but I have no experience of it. In fever it is necessary, every day, to attend to the state of the bladder. It frequently happens, in this disease, that a great accumulation takes place in the bladder; and patients might go three or four days without making water. Great inconvenience may, at last, arise from this source; and therefore it is a point that should be carefully looked after every day. There is only one other circumstance that it is necessary to attend to; and that is the longings of the patient, during the progress of the disease and afterwards. These should be indulged, unless there be some very good reason against it.

The treatment of fever, therefore, bears an analogy to the symptoms. We have seen<sup>c</sup> that the symptoms of fever vary from those of the most violent inflammation, —the most violent excitement of the system, on the one hand, down to extreme prostration of strength on the other; and the treatment must vary in like manner.

<sup>a</sup> See Page 291.

<sup>b</sup> See Page 145.

<sup>c</sup> See Page 294.

It may be requisite that the treatment should be of the most active anti-inflammatory kind, on the one hand; or the most gentle anti-inflammatory treatment, with a moderate support of the system, on the other; or it may even require to be of the most supporting and stimulating kind. Fever is not to be treated because it is *fever*; but according to the circumstances of each particular case. If we have twenty cases of fever, we are likely to find them more or less different from each other; and requiring more or less difference of treatment, according to the urgency of the symptoms. Remember, therefore, that in fever we have to vary the treatment; from that of an active inflammation, to that which is employed in mortification, when the mortification is attended by inflammation.

[Under the title of Continued Fever, our author, in common with most English writers, includes the description of what are by some considered as two distinct affections, and commonly designated at the present time under the names of typhoid and typhus fevers. The former is the principal fever met with in Paris, and has been studied with great care by M. Louis, whose descriptions accord with the phenomena which belong to common continued fever in the United States. In Great Britain, on the other hand, many cases are met with, where in certain respects this accordance is not found. Some contend that the differences here alluded to are of secondary importance, whilst others maintain that they are to be accounted for only by admitting the existence of two radically distinct fevers, as above mentioned. The question is both interesting and important, and we shall endeavour to lay before the reader a very brief summary of the facts connected with it. Let us first recall the most characteristic phenomena of typhoid fever. The disease is ushered in by chills, followed by heat, headache, and the usual phenomena of fever, accompanied most commonly by a tendency to diarrhœa. As the case progresses, these symptoms become aggravated and new ones arise; the prostration is great in proportion to the other symptoms; the intelligence dull; there is drowsiness or stupor, often accompanied by delirium; ringing or buzzing in the ears, sometimes combined with deafness; occasional epistaxis; almost always an eruption of rose-coloured spots, chiefly upon the chest and abdomen, in the course of the second week, and more or less flatulent distension of the abdomen; diarrhœa, the discharges thin, watery, yellowish or brownish, in some cases accompanied with blood; the tongue mostly pasty or dry, sometimes red, at others brown and incrustated, cracked, and protruded with difficulty. In the latter stage of severe cases, the prostration becomes very great, the discharges involuntary. Most commonly, there is throughout, a slight cough, accompanied by sonorous râle in the chest. Such are the principal phenomena of typhoid fever, which in fatal cases run their course in from eight to forty days, or even longer; and in favourable cases, gradually subside so that convalescence supervenes at various periods after the fifteenth or twentieth day. In the fatal cases, one lesion was found to be uniformly present, viz. that of the glands of Peyer. These patches were thickened, elevated and most frequently ulcerated, the corresponding glands of the mesentery being enlarged, softened and red, in every case. The disease of Peyer's patches was most marked near the ileo-cæcal valve, and their elevation was due not merely to thickening of the mucous, but also of the sub-mucous tissue. Corresponding with this description are the phenomena observed in the common continued fever of the United States, in which also the disease of Peyer's glands is found to be uniformly present. In a large number of cases, however, of continued fever as it occurs in England, this lesion is not met with, and hence the English physicians have generally regarded it as an accidental complication, and not at all entitled to the rank of an essential lesion. But as already remarked, it is maintained by some that there are in England two distinct fevers, one of which is true typhoid fever, characterized by the lesion in question, the other a distinct disease which may be called typhus.

An epidemic of the latter character occurred at Philadelphia in the year 1836, precisely similar to that met with in a set of cases introduced from certain emigrant vessels arrived from Great Britain, especially Liverpool, where the disease prevailed

at the time of sailing. This epidemic has been described by Dr. Gerhard, who found it totally different in some of its symptoms from typhoid fever, whilst at the same time the lesion of the glands of Peyer, characteristic of the latter disease, was absent. That it was similar to the typhus fever which prevails so extensively in Great Britain is generally acknowledged, and indeed has been satisfactorily established by accounts which have since been published of the fevers of that country. We shall now notice the prominent features pointed out by Dr. Gerhard and others who have succeeded him in the investigation of this question, as characteristic of typhus. In both, the nervous system is disturbed, but at times at least, if not uniformly, this disturbance is greater in typhus than in typhoid fever. Thus the stupor may begin earlier and constitute generally a more prominent symptom, the deafness be more severe, whilst subsultus and spasmodic tremors are more frequently present. The eruption in typhoid fever consists of a few oval rose coloured spots, easily disappearing under pressure, slightly elevated and generally limited to the chest and abdomen, whilst in typhus it is more abundant as well as more general, occupying the extremities as well as the trunk, of a more dusky colour, and but partially, if at all disappearing under pressure. It shows itself at an earlier period also, according to Dr. Gerhard, generally as early as the fourth day. The dusky suffusion of the face and deep injection of the conjunctiva are much more marked in typhus, thus giving to the countenance an expression which of itself is more or less characteristic. Instead of the abdominal symptoms of typhoid fever, diarrhœa and tympanitic distension, we have in typhus, on the other hand, costiveness and an absence of tympanitis. The odour of the body is peculiar and offensive in typhus, and the heat of skin more pungent than in typhoid fever. The thoracic symptoms in typhus consist in the signs of congestion, such as feeble respiration and sub-crepitant rhonchus, whilst in typhoid fever the bronchial membrane is chiefly affected, and in consequence we have sonorous and sibilant rhonchi. The average duration of typhus is less, and death often takes place earlier than in typhoid fever. As regards the post-mortem appearances, it has been already mentioned, that the lesion of Peyer's glands is absent in typhus, in which indeed, no lesions have hitherto been noticed, but such as are common to other acute affections. The most striking of the post-mortem appearances in typhus, is the great frequency of congestion, particularly of the lungs, and also of the brain. The blood is fluid and dark coloured. Such are the principal phenomena of typhus, which are certainly sufficiently peculiar to justify us in regarding it as probably distinct from typhoid fever. This view is still further confirmed by other considerations. Thus typhus attacks persons somewhat advanced in life, more frequently than typhoid fever; it occurs more frequently as an epidemic, also, and is much more evidently contagious. The treatment too as a general rule must be more tonic and stimulating, and it should further be observed that the influence of remedies is more decided and prompt in this than in typhoid fever. As regards geographical distribution, both diseases, as before remarked, are constantly prevalent in Great Britain, whilst on the continent of Europe and in the United States, where typhoid fever is of constant occurrence, typhus is met with only as an occasional epidemic. Indeed the disease can hardly be said to belong to this country, for it is doubtful whether the spotted fever which prevailed in New England as well as further south in the early part of the present century was really typhus, and since that period it certainly has not prevailed to any extent. In Philadelphia, the disease presents itself to our notice chiefly in the persons of emigrants, mostly from Ireland, or of those likely to have had intercourse with them. Even the epidemic of 1836 was very limited in extent, being in great measure confined to a very circumscribed district, the St. Giles of Philadelphia, inhabited by the most degraded portion of the population.

To the American practitioner, therefore, this form of fever is practically of little interest; but in view of his correct appreciation of the descriptions of continued fever by those English authors whose works are current among us, it is highly important that he should be aware, that under the one title, they describe two dis-

tinct fevers; one of which, only, is commonly met with in this country. Without this knowledge, he would necessarily be at a loss to account for the discrepancies which exist between their descriptions, and the phenomena of continued fever, as presented to his notice. The question which we have been considering, is, moreover, one of great interest, in its bearing upon a number of questions connected with the history of both typhus and typhoid fevers. If these affections be really distinct, it is evidently of the utmost consequence that the point should be well understood; and their distinctive characters thoroughly appreciated. The idea of such a distinction is nothing new. Thus, we find, that petechial fever, or petechial typhus, has been considered by the most profound practical men, as being a disease *sui-generis*. It is thus that Pringle speaks of the jail-fever which he describes. Huxham speaks of the great difference between what he calls the putrid malignant and slow nervous fever; the want of which distinction, he insists on, as the source of no small errors in practice. Dr. Armstrong speaks of typhus as specifically distinct from common continued fever; and says, that the dusky skin of the former is so very characteristic, that he thinks he could, by it, at any time distinguish the disease from common continued fever. However, it is only within a few years, since diagnosis and pathological anatomy have been so assiduously cultivated, that the precise line of distinction which we have briefly sketched, has been accurately made out. But whilst the points of difference, to which we have alluded, are in the main, admitted, it is still contended by some, that they indicate nothing more than varieties of one and the same affection. So long, however, as we find in the one, a certain train of symptoms during life, uniformly accompanied by a peculiar morbid alteration after death; and in the other, not merely a different set of symptoms, but a corresponding absence of the anatomical characteristics of the first; it seems to us unreasonable not to admit a radical distinction. Such is the conclusion to which we are brought by the paper of Dr. Gerhard, before referred to, as well as by Dr. Shattucks' account of the cases of typhoid and typhus fever, observed by him in London, in the year 1839. The same is maintained by Dr. Stewart, who had observed both diseases at the Glasgow fever hospital; by Dr. Staberoh of Berlin, and others who have had an opportunity of observing these diseases, both in England and on the Continent. The personal experience of the writer, inclines him to the same opinion. The cases of typhus fever admitted into the Pennsylvania Hospital, occurring chiefly in the persons of emigrants just arrived from Great Britain, have, indeed, always appeared to him so distinctly marked, as scarcely to admit of being confounded, except by a superficial observer, with typhoid fever. I would not, however, be understood as maintaining that the question is settled. Men of acknowledged merit entertain an opposite opinion, and consider the two affections to be but different forms of one and the same disease. Professor Rokitski<sup>a</sup> adopts the latter opinion; and maintains, as the result of his anatomical investigations, that this disease is characterized anatomically, by the deposit of a peculiar substance, analogous to medullary sarcoma, and that its different forms are dependent upon variation in the seat of the deposit, the common source of which is to be found in a peculiar diseased state of the blood. When this deposit takes place in the ileum, the disease is called ileo-typhus (typhoid fever), in the bronchial glands, broncho-typhus, the same probably as what we have spoken of under the title of *typhus*. These results need confirmation.

Before concluding these remarks, let us observe that we agree with Dr. Elliotson, in regarding the local lesions in fever, as secondary, and altogether inadequate to account for the origin and progress of the symptoms. Still, we think that the lesion of the glands of Peyer holds a rank distinct from the common secondary lesions, in this, that it is peculiar and essential, thus constituting the anatomical character of the disease, and having probably much the same relation to the latter, as the pustules of small-pox have to that affection. Those of our readers who wish to be made more fully acquainted with the distinctive character of the typhoid and

<sup>a</sup> American Journal of Medical Sciences, No. xi, July, 1843.

typhus fevers, and with the nature of the evidence by which the essential distinction is maintained, will be amply rewarded by the perusal of the work of Professor Bartlett,\* lately published. T. S.]

## CHAPTER VI.

### REMITTENT FEVER.

*Its Nature.*—I now enter upon the subject of *remittent* fever; which resembles both *intermittent* and *continued* fever; and partakes of the character of each. Essentially it is the same as *intermittent* fever. It arises, I believe, from the same cause,—malaria; but—either through a modification of the malaria, or the influence of such causes as predispose to, or excite, *continued* fever—we have only remissions;—not *intermissions*, but *remissions*. The disease is really *continued*, although *remitting*;—having a relaxation of severity at different hours. This disease occurs in hot climates particularly; and in cold climates during hot seasons. It therefore occurs when and where there is the greatest abundance of vegetable matter; and where there are all the circumstances most favourable for decomposition, and the production of *aguish* fevers; and, also, where there is the greatest prevalence of those causes, which are likely to excite *continued* fever;—excitement and relaxation of the body, and disturbance chiefly of the abdominal organs. Many epidemics described, in ancient books, as plagues and pestilences, were really remittent fevers.

*Symptoms.*—There is continual fever every day throughout the twenty-four hours; but the patient is much less hot at one time, than at another; so that, although he has constant feverishness, he feels himself far less ill at different intervals. Sometimes, in addition to the continual fever, there is a regular paroxysm of ague. I have seen a person constantly hot day and night; except, perhaps, every *other* day; when he had a cold fit; and then the heat would become more intense, and sweating would occur. But when the latter was over, there was no intermission; for the patient was hot again. The usual form is continued feverishness; with a great aggravation of it at particular periods. Or (to put it in another way) we have the symptoms of continued fever; but there is a relaxation of these symptoms at particular periods. But besides this, (although I do not recollect its being described), I have seen continual fever, with a paroxysm of ague coming on, at regular intervals, in the midst of it.

Sometimes, instead of remissions alternating with an aggravation of the feverish symptoms, the remittent nature of this continual fever is shown only by occasional chilliness. I have frequently discovered that *continued* fever (as it appeared to be) was really *remittent* fever, by noticing that, although there was continual feverishness, heat, and thirst, yet the patient, in the midst of it, was frequently chilly; and on other occasions by observing that, in the very midst of the heat, there was from time to time profuse perspiration. The nature of the disease was pointed out to me, either by the occurrence of chilliness (even amounting to rigors) from time to time, or by the occurrence of sweating at intervals. The correctness of this opinion has been proved, by giving the patient quinine; which has restored him to health. So far as my own observation goes, I think, that remittent fever shows itself sometimes in these two forms. Intermittent fever will become *remittent*, if the cause of *continued* fever be superadded, after *intermittent* fever has begun. Supposing a patient has ague, and goes through great fatigue or want of rest, or is

\* The History, Diagnosis and Treatment of Typhoid and Typhus Fever, &c. by Elisha Bartlett, M. D., Professor of the Theory and Practice of Medicine in Transylvania University, Philadelphia, 1842.

exposed to wet or cold, he may be thrown into continued fever. These circumstances alone would not cause ague; but as ague already exists, the disease becomes remittent fever. The causes of *continued* fever, are applied to a constitution labouring under *intermittent* fever; and then we have *remittent* fever. Frequently, however, the disease is produced from the very first.

When remittent fever is acute, it seldom (I believe) lasts more than six weeks.

*Varieties and Duration.*—Dr. Macculloch, however, imagines that remittent fever is often a chronic affection; that it is often mistaken for hypochondriasis; and that the paroxysms are not observed, because they occur in the night. I am persuaded he is correct. I am persuaded that many persons have long-continued remittent fever;—frequently for many months; and, its true nature not being detected, it is thought to be some indescribable complaint. I had under my care a patient, who appeared to be in this state;—a man who was frequently very hot; complained of heaviness in the head; was affected in his mind; and had great depression of spirits. This man took five grains of sulphate of quina, three times a-day, without any effect; but, on increasing the dose to ten grains, I found him better. I have seen many such cases; and they long puzzled me. They are principally characterized by oppression of the head, heat occasionally in the night, and great depression of spirits.

*Aggravated Form of the Disease.*—The disease in its acute form frequently assumes a very aggravated type; as dreadful for rapidity as violence. It is in hot climates, particularly, that this occurs. This form of the disease is so violent, and so acute, that there is at first delirium and violent vomiting; with an absolutely roasting heat in the stomach; and great pain, tenderness, and agonizing distress, at the epigastrium. Besides these local symptoms of the head and the stomach, there are all the signs of a violent inflammatory fever; and these symptoms, both local and general, are soon followed by the most awful debility, and by all the signs of typhus.

*East Indian Fever.*—The fever of the East Indies is a violent and acute remittent fever;—accompanied by great derangement of the liver and stomach; and occurs in various other parts of the East besides Bengal. At Bengal it arises from the overflowing of the Ganges, and the subsequent fall of the waters, acted on by a high temperature. After the Ganges has overflowed, the waters fall in November and December; and, in consequence of the heat, such emanations are produced as to cause this fever. The violent delirium, pain, and vomiting are succeeded, after a certain time, by a remission and a sweat. This occurs about twelve or fourteen hours after the attack; and the pulse, from being 130, may fall down to 90; and then the delirium ceases, and the mind is restored. The remission, however, is but short; for the symptoms soon reappear; and are then succeeded by the awful debility to which I have referred. If the disease prove fatal, there is very soon no remission at all. The gastric symptoms become more violent than before; the tongue becomes black; the pulse small; and the patient sinks. If it be fatal, it generally proves so (we are told) between the third and the seventh day; but occasionally it has been known to last fifteen, or even twenty days. Of course, I am only speaking from information which I have derived from authors.

*Yellow-Fever.*—This disease has appeared, with some other symptoms, in the Mediterranean, in North America, and in the West Indies. In the Mediterranean it has appeared at Rochfort, Bourdeaux, Lisbon, Gibraltar, and Minorca. In addition to the symptoms I have already enumerated, the fever is characterized, in these countries, by yellowness of the skin, and a vomiting of black matter. Thus varied, it has been called “yellow-fever,”—from the yellowness of the skin. In America it is said that thirty-six, or even seventy-two hours, generally elapse before the remission takes place.

*The Black-Vomit.*—The black-vomit, which is as much characteristic of yellow-fever as the yellowness of the skin, is thought to be bile a little changed from blood;—imperfectly formed bile; or even blood only a little changed. Indeed, some suppose that, of the two, it would be more proper to call it “*blood*” than “*bile*.” It

is said to have been found on the surface of the stomach, when there was none in the duodenum;—as though it had not come from the liver. This black-vomit is said to be by no means acrid. Dr. Physie, of America, says it is tasteless; and that he dropped some into his eye, and the organ did not become irritated. He also says that he found an abundance of it in the stomach, when a different fluid was observed by him, both in the gall-bladder and the gall-ducts. It is decidedly of the appearance of charred blood;—of blood that has undergone certain changes, and is poured forth from a mucous membrane. Another gentleman has carried his experiments, with the black-vomit, farther. Dr. Firth tells us that he procured two ounces from a patient (whether dead or alive I do not know); that he drank it undiluted; and found it harmless. Before this he had drunk a large draught of it, mixed with water, with impunity; but he took two ounces in its genuine state, and said he was none the worse for it. He wished to try it in a solid form; and therefore made an extract into pills; and he says that he found as little inconvenience from them, as he had previously done from his “black draughts.” The fluid and concretion of melanosis, also, are generally inert.

*Yellowness of the Skin.*—The yellowness of the skin is ascribed by some to bile pervading the system; but there are very great doubts as to whether that is its origin. The bile is very abundant in this disease; and may be regurgitated, by violent vomiting, into the veins, through the compression of the parts; but there is no obstruction. At any rate, it is certain that, if it be bile, it is not obstruction that produces regurgitation of it; for the fæces are well tinged with bile. One reason for saying that it is not bile, is that it will occur in patches. It is not more visible in the eyes and nails, than in other parts of the body; and it is not diffused equally throughout the body, as we observe in jaundice; but occurs in patches, as ecchymoses would do. It would appear rather to owe its origin to the blood being changed;—to the serum, with a few red particles, escaping more or less into the cellular membrane;—the blood having undergone a change. It is altogether analogous to ecchymosis, when nearly gone; and we know that an ecchymosis does not arise from bile; but from an effusion of blood, that is subsequently in a great measure absorbed;—the portion which remains giving a yellow colour. Sir Gilbert Blane says, that when yellow fever prevailed in the West Indies, he has observed it spread from bed to bed; and that it bore no proportion to the malignity of the disease. It appeared in two vessels (the Alcides and the Royal Oak), when there was only a slight indisposition. He also says that, unlike jaundice, it begins usually about the parotids. There is usually fulness and flushing of the face and neck; but particularly about the parotids. Here there is the most blood; and here it is that the yellowness appears in the most distinct manner.

*Climates and Seasons most liable to Yellow-Fever.*—This yellow-fever (or “causus icterodes,” as some call it) is apparently another form of bilious remittent fever; and occurs only in countries and in seasons, where the heat is such as would destroy or arrest the plague. It occurs, too, in hot seasons;—such as would usually put an end to contagious typhus-fever, when that is prevailing. Yellow-fever, and bilious remittent fever, are always extinguished by cold weather. As soon as the cold sets in, they cease.\* It is said that the blacks, in America, are usually less violently affected than the whites; but that if they go into a cold country, and reside there for a time, and then return to America, they suffer equally with the whites. Persons who are unaccustomed to a high temperature, it appears, suffer most from this disease. Blacks coming from hot countries, or having descended from parents born in hot climates, suffer less; but if they reside in cold climates, their constitution partakes in some degree of that of the white; and then they suffer far more than others of their black brethren.

\* There is nothing, connected with yellow-fever, which seems so invariable as the decline of the epidemic on the setting-in of cool weather. At a temperature of about 50° (Fahrenheit), fresh cases soon cease to appear; and, in Spain and North America, the disappearance of the disease at a particular period, is usually calculated on with precision.—*Dr. Gil krest, on the Yellow Fever; in the “Cyclopædia of Practical Medicine,” Volume 4, Page 279.*

Cold countries, and the cold seasons of hot climates, are free from this disease. It generally occurs only in the tropics, and elsewhere when the heat is as high as in the torrid zone; but very intense heat, in cold climates, has been known to occasion it. If the temperature have accidentally been as high as in a hot country, then even a cold climate has been subject to it. Sir John Pringle, for example, says that he has sometimes seen yellowness of the skin in Flanders. Dr. Brocklesby mentions seeing it, in 1758, in the Isle of Wight. Dr. Home saw it at Worms, in Germany, in 1743. It prevails in the West India Islands, in Charleston, Norfolk, Providence, Philadelphia, New York, Baltimore, and Boston. Those places that have the largest quantity of vegetable matter for decomposition, when the hot weather comes, and have the most moisture, are most subject to this yellow-fever. It occurred at Lisbon till the earthquake happened. It occurs also at Cadiz, Bourdeaux, Rochefort, Seville, and Gibraltar. The latter place is situated high enough; but although high in reference to the sea, the town is low in reference to the mountains. The rain that runs off four thousand acres, it is said, streams towards the town; bringing with it a quantity of vegetable matter from the hills, as well as fragments of vegetable refuse from the markets. Even straw has been said to afford the source of this disease at Gibraltar. Sir John Pringle says, that the straw was very injurious to the army there. The rocky soil increases the mischief, as it causes the water to remain.

*Causes of Yellow-Fever.*—However, notwithstanding it would appear that yellow-fever is the product of malaria, there has been a difference of opinion on this subject entertained at different times. A Mr. Vines, a planter and “physicker” in the West Indies in 1647, writing from Barbadoes, ascribes the yellow-fever to “the Lord’s heavy wrath;” and not to any thing in the climate. The island was not cleared for a considerable time after he wrote. The disease prevailed then, to a greater extent than it does now. A Spanish officer named Armesta, who ascribed the disease to local situation and atmospheric causes, was actually at one time arrested; and was obliged to retract his views, as being “false, dangerous, and seditious opinions.” So violent, at one time, was the opinion that it had nothing to do with local situation, that fifteen hundred copies of this officer’s book were burned. In the year 1800, the government had a different opinion; and ascribed it to something in the atmosphere. And this is really the case; for it is owing to miasmata.

*Is Yellow-Fever Contagious?*—A great question has arisen in the western hemisphere, and in the Mediterranean, as to whether yellow-fever is contagious or not. Dr. Firth, of Philadelphia, who tasted the black-vomit in the way I have stated,\* says that he has frequently inoculated himself with it; and also with the serum, saliva, &c., of patients labouring under the yellow-fever; but that no prejudicial effect was produced. It is said that it is never propagated a mile from Philadelphia; and that therefore it must owe its origin to local causes. Dr. Rush—who was a celebrated American physician, and a violent contagionist—contended that this was a contagious disease. He afterwards retracted his opinions; and begged the forgiveness of the friends of science and humanity, if the publication of his former opinions had had the effect of increasing the miseries attendant upon the disease. He says, indeed, that such is the pain he feels in recollecting that he ever entertained or propagated the opinion of its being contagious, that it will always lie heavy at his heart; and deprive him of the pleasure that he might otherwise have derived, from a review of his attempts to fulfil the duties of his public station. He says he was misled by Dr. Lining, and other writers. “I am aware,” he says, “of the influence which changes in opinion have upon a medical man’s reputation; but still I would cheerfully make a sacrifice of that kind, could it avert the evils which are connected with the belief of its being a contagious disease.” The mode in which a false belief in contagion does harm, is by preventing the healthy from attending upon the sick; by stopping commercial intercourse; and by allowing the patients to remain in the unhealthy spot, which really causes the disease.

\* See Page 334.

It is impossible for us who live here,<sup>a</sup> to know any thing about these matters; for there is as much evidence on the one side as on the other. In the East Indies it is never thought to be contagious; but in the West Indies it is so considered, by a large number of persons. The fever in Gibraltar gives rise to a diversity of opinion; and there are as many protestations as to its being contagious, as there are as to its arising from malaria. Dr. Stevens thinks that he has discovered the reason of all these discrepancies of opinion. He says there are three distinct yellow-fevers in the western hemisphere. In the first place, there is one in which there is no contagion at all; but which is a climate-fever; and arises simply from excessive heat. It occurs to new comers, who are operated upon violently by the intensity of the temperature. Severe bilious symptoms arise; but he says there is nothing contagious in it. He contends, next, that there is the remittent fever; the *yellow-fever*; arising from the local cause of malaria and heat together;—a fever which is seen by every body, and acknowledged to exist by most. Besides these, he says there is a yellow *typhus-fever*; which he has been able to trace to the negroes in America, who have come from Africa. It is a contagious disease, attended with yellowness of the skin, and brought there by the Africans. He says that all these three fevers are attended with yellowness of the skin. What his observations are, or how numerous they may be, from which he has drawn these conclusions, I cannot tell. He says that the symptoms of these fevers are all different at first; but after a time they are all the same; and that although the general treatment of the whole is the same, yet (as they differ in their minutiae) they require a modification of treatment. I cannot say more upon this subject. I give no opinion upon it; but I should think it likely to be the case;—that there are two or three different kinds of fever; and that the intensity of the heat occasions them *all* to be characterized by great yellowness of the skin, *some* by a depraved state of the blood poured forth under the skin, and *others* by jaundice. I have no doubt that Dr. Stevens has founded his opinions on numerous facts; and that many of them will be found well established. I believe that the greatest authorities in America are satisfied that the yellow-fever (as it prevails there) is, for the most part, not contagious; but that it is *sometimes* contagious, appears very certain.

*Dr. Stevens's Opinions on Contagion.*—In a conversation which I had with Dr. Stevens, he mentioned an instance of yellow-fever occurring in a family, situated at a great distance (across the sea) from any place where the disease had prevailed. The captain of a vessel was in a port, where yellow-fever prevailed; and, being continually among the people, his clothes and his linen were impregnated with it. I am not sure whether he had the disease himself; but he had been in the midst of those who laboured under it. When he left the port, he cheated the quarantine; and went, with his linen unwashed, to another place, where no fever had prevailed. According to the quarantine regulations, his linen should have been washed; but I understand that, under those regulations, washing is very dear; and that every thing is charged double. He, therefore, to save his double expense, contrived to take some of his dirty linen with him;—satisfied that the disease was not contagious. The linen was taken out by his family, in this place where yellow-fever had not prevailed; and, in a very short time, one and another of the sisters and maids who washed it for the captain, died; and an old woman who lived in another part of the country, and came to help them, was also seized with the disease. It spread from house to house, all through the town; and produced very great devastation. Dr. Stevens says, that he knows it was the contagious form; that, in fact, it was what he calls “African typhus.” He took a voyage for the purpose of inquiring into the circumstances. The sisters said that it arose from the dirty linen; and it appears that he was able to trace it with the greatest accuracy. He also mentioned his opinion that *cholera* is contagious; but he is satisfied that the contagion is not efficient *at first*. He says we may be exposed to a person labouring under “African typhus” (as he calls it), or to a person labouring under cholera, without

<sup>a</sup> In England.

any fear of catching it, while in his *first emanations*; but that if exposed to these emanations after they have continued to pass from him many days, then we stand a chance of getting the disease. He considers that what proceeds from the body is not, at first, efficient;—that it is not a perfect poison when it is first produced; but that it undergoes a change, which enables it to produce the disease. He reasons in this way. Many persons who have visited cholera-patients, have escaped; but they have suffered as soon as they have been exposed to fomites, in which the secretion was contained. How that may be, I do not know. He also says that he has ascertained another circumstance;—that, before the disease breaks out, the blood will show the disease. He says that this may also be remarked in scarlet-fever. A medical man, finding that he was ill, was bled. The blood was shown to Dr. Stevens; who found that it would not turn red with the usual neutral salts. He stated that he was satisfied the gentleman was about to have a contagious disease; and, in three or four days after this, scarlet-fever occurred. He says that he has seen yellow fever in the blood, before the disease appeared; and that, in all instances where the disease subsequently appeared, he found the blood was of such a character, that it would not redden on the application of a mixture of neutral salts. Of course, all these things are exceedingly crude at present; but it is the opinion of many eminent chemists, that we are upon the eve of some important discoveries, with regard to the nature of all these matters;—that, by the treatment which Dr. Stevens has recommended, great light will be thrown on the pathological changes, which take place in the various fluids of the system; and on the nature of many diseases. I feel satisfied with the truth of much that has been said; and I feel satisfied that a strong and new light will be thrown upon a number of these matters, respecting which we are all at present in the dark. The latent period of this yellow-fever, is thought to be from two to ten days.

*Treatment.*—With regard to the treatment, the best writers agree that, in the first instance, there should be copious venesection. Whether it be the fever of the western hemisphere, or the mere bilious remittent of the east, cold affusion, or cold *ablution*, is always serviceable. Great attention should be paid to any local inflammation that may occur; and local bleeding may be demanded. As to emetics, they cannot be employed if there be any tenderness of the epigastrium on pressure. Mercury is found useful in the first instance; but not afterwards. When there are symptoms of violent inflammation, it is very useful; but still a person may die with his mouth sore, if it be given too late, or bleeding to a proper extent be not practised. Of course moderate purging is necessary; but as soon as the remission occurs, sulphate of quina should be given in great abundance; and Dr. Stevens says, that when the symptoms of typhus-fever come on,—after venesection, and mercury, and cold affusion have been freely had recourse to,—no time should be lost in pouring in neutral salts. He says he has strong evidence to show that, where these fevers had proved fatal to a frightful extent, the mortality has been reduced almost to nothing, by practitioners having listened to his advice. By giving neutral salts (as the carbonate of soda, the chlorate of potass, and common salt) every hour during the disease, the beneficial effects has been infinitely beyond what any one could have anticipated. I know that this gentleman states nothing as a fact, but what is strictly true. If he merely give an *opinion*, of course (like other men) he may be wrong; but upon whatever he states as a *fact*, the greatest reliance may be placed; and if he say that a certain number of cases out of the whole number have been cured, the statement may be depended upon as correct.

*Sol-Lunar Influence.*—Before I conclude the subject of these fevers in hot countries, I must mention that, in the East Indies, the sun and moon appear to have a great influence upon them. Dr. Balfour has written a work upon what he has called “the sol-lunar influence;”<sup>a</sup> and he proves that bilious remittent fever is most easily taken at new and full moon; that at new, and full moon the disease is greatest, and relapse most common; and that those suffering from “pernicious fever,”<sup>a</sup>

<sup>a</sup> “Treatise on the effects of Sol-Lunar Influence in Fevers, &c. By William Balfour, M. D.”

which has destroyed the constitution, are particularly affected at that period. This may appear incredible or whimsical; but I have no doubt of the fact. I have seen medical men who have practised in the East Indies; and they say it is well enough for us not to believe it; but they have suffered enough to know that it is perfectly true. I do not suppose that it is to be ascribed to the direct influence of the sun and moon upon the body; but that it arises from the operation of these upon the tides. The new and full moon, with respect to the elevation of the water, may have very great effect; and the tides, again, may have an effect, by causing more or less malaria to be disengaged; so that the atmosphere is more impregnated with it at those periods, than at others. I believe there can be no doubt whatever on the subject;—that at new and full moon, in the East Indies, fevers are most easily taken, relapse is most common, and fevers are most intense; and that those who have suffered most from these fevers, then feel a strange sensation about them;—just such as we continually find here, when the east wind blows upon a person who has previously laboured under ague.

*Remittent fever. (Dr. Stewardson).*

[Remittent fever is one of the principal diseases of the middle and southern sections of the United States. I agree with Dr. Elliotson, in believing that essentially it is the same disease as intermittent fever, at least so far as this, that both depend upon a common cause, and possess certain common and characteristic features, which at the same time distinguish them from other fevers.

No disease, probably, presents itself under such varied aspects in different climates, localities and seasons, and hence besides those designations which directly indicate some predominant feature, as the inflammatory or bilious, we often find it referred to under the title, for instance, of Walcheren, Mediterranean, or Carolina fever, according to the country in which it has prevailed. I shall not undertake to give even a summary view of the precise forms which the disease assumes, in these different localities. Such a course, indeed, could be of little service in enabling the reader to appreciate the general features of the disorder; and besides, there is always great risk, that in endeavouring to condense and combine the more enlarged descriptions of particular epidemics or endemics, which we have not ourselves witnessed, we may compose a disjointed description, which will be far from being true to nature. I therefore prefer to examine separately the principal phenomena of remittent fever, and especially such as are more particularly characteristic of it; in doing which, I can appeal in part to my own observation.<sup>a</sup> Yellow fever is not included in this description, because I regard it as a totally distinct affection, and shall give a separate account of it.

*Symptoms.*—Remittent fever is commonly ushered in by a chill, which sometimes does not amount to more than a sensation of coldness. Sometimes there is no recurrence of chills, whilst at others they are repeated at intervals of 24 or 48 hours, for the first few days, and then disappear altogether; or again they may reappear during convalescence, and sometimes at intervals during the course of the disease. According to my own observation, where this recurrence takes place, it is most commonly at the tertian period. During the febrile exacerbation, the heat of skin, though often great, is rarely pungent, whilst during the remission it is often natural, or even less than natural, and accompanied by perspiration, which sometimes, especially towards the conclusion of the attack, is very profuse. The febrile exacerbations, though occurring daily, are commonly most marked on the alternate days, at which time we usually find a manifest augmentation of all the symptoms. The remissions vary very much in degree, and although generally very marked, are sometimes not readily perceived, or may for a time entirely disappear.

<sup>a</sup> See Page 269.

<sup>b</sup> The results of the writer's observations on Remittent Fever were published in the American Journal of the Medical Sciences for April 1841, and April 1842.

The pulse of course varies exceedingly, being more or less frequent during the exacerbation, scarcely exceeding the natural standard, or even falling below it, during the remission. On the whole it is less rapid than in proper continued fever. As regards other characters, such as softness, fulness, &c., they vary exceedingly under different circumstances.

As the disease progresses the skin is disposed to assume a sallow, and especially in the more malignant bilious form, a yellow colour. In the pernicious or congestive form, it is more apt to assume a pale or leaden hue. I have never in a single instance noticed rose-coloured spots, so frequent in typhoid fever, and although sudamina are occasionally met with about the neck, they are much less frequent than in the latter disease. The dusky eruption of typhus too, is, so far as I am aware, entirely absent in remittent. It is true that in the most aggravated form of the latter, petechiæ are sometimes mentioned as occurring towards the conclusion; but these were no doubt true petechiæ, such as are at times present in various affections, and very distinct from the proper eruption of typhus.

Pains in the back and limbs are the usual concomitants of the disease at the commencement. So also is headache, which usually persists during the early period, or even longer, like most of the other symptoms, however, being most marked during the exacerbations, subsiding or disappearing entirely during the remissions. The mind is not often much affected. There is wandering of course at times, during the violence of the exacerbation, and occasionally active delirium; but in the main the intelligence is not disturbed. Stupor also is sometimes present, and may even be very profound, but is not often of long duration; and like delirium does not exist as a prevailing feature. In these respects there is a remarkable difference between remittent and typhoid fever. Instead of the steadily increasing wandering, stupid expression, and slow answers met with in the latter, we have for the most part in remittent, an intelligent or even active expression, with prompt answers, the sense of hearing being commonly unaltered. Such at least is the case in our ordinary remittent, so far as my observation extends, and essentially the same appears to be true of the disease generally in its common form, judging from the descriptions of authors. As regards delirium, however, it should be observed that it is spoken of as a very prominent feature in some epidemics. Thus we are told by Pringle, in his account of the intermitting and remitting fevers of the camp, that in some instances the head was so suddenly and violently affected, that without any previous complaint the men ran about in a wild manner, and were believed to be mad, till the solution of the fit by a sweat, and its periodic return, discovered the true nature of their delirium. Again, in the pernicious form of the disease, the patient is often thrown into a state of stupor or lethargy; but here as in the previous instance, the affection is more or less prompt in its onset, and subject to as rapid abatement, which circumstances, together with the different expression of countenance, the general absence of deafness, &c., sufficiently distinguish the cerebral disturbance of remittent, even when present to a considerable degree, from that of proper continued fever, whether typhus or typhoid. Sometimes, it is true, the delirium of remittent is spoken of as progressive and permanent, but only in the latter stage of severe cases. The thoracic organs mostly suffer but little. Not so, however, the abdominal viscera. Nausea or vomiting, indeed, are among the earliest and most frequent symptoms. The matter vomited is commonly bilious; but in those cases which have been styled hepatic remittents, there is an absence of bile in the matters evacuated, whether by vomiting or stool, until towards the close of the attack, when in favourable cases there are large evacuations of dark pitch-like matter, which have been regarded as critical. Costiveness generally prevails, but sometimes at the commencement there is free spontaneous purging.

Besides the nausea or vomiting, a painful sense of weight and tension in the epigastric and hypochondriac regions, particularly the right, with oppressed and anxious respiration, are usually described as among the most prominent symptoms. In severe cases the epigastric anxiety and oppression are often extreme, and sometimes they are noticed in conjunction with deadly sickness, as perfectly intolerable. Even in the milder forms of the disease, I have generally found more or less ten-

derness of the epigastrium, and frequently of the left hypochondrium, the latter probably being chiefly dependent upon enlargement of the spleen, which enlargement, I suspect, can generally be detected, if carefully sought for through the aid of percussion as well as the touch.

Meteorism is said to be frequent in the latter stage of those cases which assume an aggravated form. Such, however, does not appear to be the case in the milder forms of the disease. For myself, I have almost always found the conformation of the abdomen natural, unless when there was some fulness about the epigastric and hypochondriac regions, and indeed in the only case, accompanied with considerable meteorism, which I recollect to have met with, this state was, I think, especially marked above the umbilicus.

The state of the tongue is very various; so far as I have observed, there is much less tendency to its becoming dry, chapped, brown, or preternaturally red, than in typhoid fever, but in the most severe forms, it is described as becoming dry and black and accompanied with sordes about the teeth.

The last circumstance to which I shall allude, is the tendency to yellowness, which is especially marked in the conjunctiva. Sometimes this tinge is not at all observable in the skin, which at other times is sallow, or positively yellow. In some severe cases the whole surface of the body is of the colour of brass. The same bilious impregnation is met with in the urine, to say nothing of the contents of the stomach and bowels already mentioned.

*Varieties.*—It has been already remarked, that under different circumstances the disease assumes very different aspects. In its simplest form, such as it occasionally presents itself in temperate climates, the symptoms are generally mild, the epigastric distress moderate or even entirely absent, the biliary functions but little disturbed, and the complexion little or not at all altered. The type of the fever is mostly double tertian, the remissions being most marked on the alternate days. The remissions are sometimes very complete, more so in some years than others, whilst again they may be so indistinct as to give to the disease a pseudo-continued aspect. Still, however, the practised observer will generally be able to detect its periodical character during a part of its course, especially by watching the character of the remissions on alternate days. These cases may run on for several weeks, and where the remissions are indistinct, may readily be mistaken for mild cases of typhoid fever. From the latter they may be distinguished by the clearness of the intellect, the comparatively natural expression of countenance, and the absence of deafness, of rose-coloured spots, of meteorism, and of diarrhœa, all which constitute such prominent features of typhoid fever.

In another and more prevailing form, which may be styled simple bilious remittent, the bilio-gastric symptoms already described are more marked, the breathing oppressed and anxious, the eyes assume a yellowish tinge, and the symptoms generally become more aggravated. Between this and the bilious remittent of the highest grade, there are many transition shades. In this latter, the symptoms are most violent, and often rapid in their course. The pains in the head, loins and limbs, are excruciating, the sickness deadly, with great epigastric distress, restlessness and oppression, the heat of skin during the exacerbation pungent, its yellow colour becoming of a deep shade as the disease advances, whilst towards the conclusion petechiæ and vibices are said to make their appearance, the tongue becomes covered with a black crust, the teeth with sordes, the breathing laborious, the anxiety extreme, and finally the extremities become cold, and death closes the scene, most commonly from the fourth to the eighth day.

Besides the various shades and varieties of bilious remittent, there is another very distinct form of the disease, described by the continental European writers under the title of pernicious, and generally known among us as congestive fever. It is sometimes described under the head of malignant, but this term is also employed to designate any very violent form of disease, without reference to its particular character. The pernicious or congestive remittent is especially characterized by symptoms of great prostration and congestion. The patient is lethargic, drowsy, or even comatose; the countenance is swollen, the respiration is oppressed, there is

nausea or vomiting, with anxiety, faintness, diarrhœa, &c. During the chill, which is often accompanied with icy coldness, the pulse is scarcely to be felt, and when the fever supervenes, it develops itself but slowly, being weaker, smaller and softer than in ordinary cases. During the remission, it may even be slower than natural. As the disease advances, the remissions become more and more indistinct, till they are scarcely perceptible, and the fever becomes pseudo-continued. Prolonged and cold perspiration, cold livid extremities, &c. often mark the concluding stages. Where these symptoms are extreme, it is sometimes called the cold plague, and may prove rapidly fatal.

Such are the most important symptoms of remittent fever in general, and of its principal varieties. It has been already remarked, that no disease assumes such varied aspects, from differences of climate, situation, and other circumstances. Sometimes perhaps we may meet with an epidemic in which the symptoms are intermediate between the more inflammatory bilious and the pernicious remittent, and such a combination would probably pass under the title of congestive in most portions of our country. To enter more into detail, however, and describe the exact combinations of symptoms which have been met with by different observers in different countries, would unnecessarily encumber if it did not confuse the subject. Enough has been said to convey a pretty distinct impression of the phenomena of remittent in general, as well as of its principal varieties.

*Duration and Terminations.*—The duration is very various. In the most malignant forms, death takes place in a few days, or even in the very first paroxysm, but more commonly it occurs towards the end of the first or in the course of the second week. Sometimes the disease is protracted for six weeks or more, with moderate fever, emaciation, sallowness or yellowness of skin, prostration, &c. Such cases, so far as I have observed, are generally accompanied by evidences of subacute inflammation of some of the abdominal viscera. The state of the stomach and spleen, as well as of the biliary apparatus, ought here to be carefully inquired into. Diarrhœa or dysentery may also supervene. In the favourable as well as in the fatal cases, however, the course of the disease is usually rapid, convalescence commonly taking place between the fifth and eleventh days, or at any rate within the first two weeks. The mean duration, according to my observations at the Pennsylvania Hospital, may be estimated at about fifteen days. But in this, as in so many other respects, there is scarcely any disease which presents so many differences under different circumstances. One thing, however, is clear, viz. that its mean duration is considerably less than that of typhoid fever, under similar circumstances. The same is true of the mortality, which in the violent forms of the affection in hot climates is very great, whilst in the simple forms in the more temperate climates it is very small. The proportion for three successive years in the Pennsylvania Hospital was one in ten and a half.

Besides the protracted form already mentioned, the disease may be converted into intermittent, and give rise to the same consecutive phenomena as the latter affection, viz. enlarged spleen, cirrhotic liver, dropsy, &c.

*Critical Days.*—Before leaving this part of the subject we will say a few words in reference to critical days. These have given rise to much disputation at different times. It seems, indeed, to be now pretty generally admitted that the commencement of convalescence in acute diseases is often marked by the occurrence of certain phenomena, particularly an increased discharge from the skin or some other emunctory, and such phenomena have been called critical. Besides, it can hardly be doubted that these acts are absolutely serviceable in bringing about the solution of the disease. But the doctrine of Hippocrates on this point,—to say nothing of his views upon the mode of production and object of these critical evacuations, views of course which are intimately associated with the hypothetical opinions of the day, and which we would not be understood as maintaining—went much farther in reference to a mere question of fact, for he maintained that these crises, especially when most favourable, were most apt to occur on certain days, as the 7th, 9th, 11th, &c. whilst the intermediate days were unfavourable. So far as the

proper continued fevers are concerned, such as typhus and typhoid, it seems well established that there is no particular tendency to abate or terminate on particular days; and these, it is to be recollected, are almost the only fevers met with in London or Paris, as well as the other great centres of modern medical doctrine. But it does not hence follow that the same is true of all fevers, or that the opinion of Hippocrates which supposes certain days to be more favourable than others, has no foundation in fact. Now as regards remittent fever, we frequently find it mentioned by authors that a favourable termination is particularly likely to take place on certain days. By Jackson, in his account of the remittent fevers of the West Indies, it is expressly stated that of sixty cases which terminated favourably, ten terminated on the third, ten on the fifth, twenty on the seventh, ten on the ninth, five on the eleventh, three on the thirteenth, and two on the seventeenth. On the other hand, of nine which terminated fatally, one terminated on the sixth, one on the seventh, six on the eighth, and one on the tenth. This perfect regularity may of course be variously interfered with; the regular tertian or double-tertian revolution, usually of forty-eight hours, may be accomplished in rather less; but if, in addition to other evidence, we recollect that most writers agree in this, that the tertian or double tertian type is the most common type of remittents, we can scarcely fail to admit that the disease has an especial tendency to terminate at particular periods, separated generally by intervals of about forty-eight hours. Now it should be recollected that the fevers with which Hippocrates was principally conversant, as we shall have occasion to point out more particularly when speaking of the diagnosis, were of periodical basis, being either distinctly remittent or only pseudo-continued, but essentially distinct from the true continued fevers, whether typhus or typhoid, of England and France. It is perfectly clear that opinions based upon the observations of these latter, however correct in reference to them, may be altogether inapplicable to other fevers, and such we believe to be the fact. At least, it seems to us highly probable that the doctrine of Hippocrates in reference to the point in question, is based upon sound observation, and applicable to that species of fever which predominates in Greece and its neighbouring islands. Much of the discussion, then, about critical days might probably have been saved if these points had been properly considered. Especially we may hence learn the importance of making proper distinctions in fevers, and of not hastily applying to fever in general, what is true only of some particular kind.

*Causes.*—The circumstances under which remittent fever arises, are much the same as those which give origin to intermittents. Both are regarded as depending upon certain emanations, styled marsh miasmata or malaria, of highly analogous, if not identical nature. The subject of malaria, however, has been so fully discussed under the head of intermittent, that I shall not further allude to it. Remittent fever is rarely met with in the centre of large cities, except in the case of individuals who have been exposed to its causes elsewhere. This, we are convinced is true of Philadelphia, in the neighbourhood and on the outskirts of which the disease prevails uniformly to a greater or less extent in the fall of the year, whilst at the same time it is rarely if ever met with in the heart of the town, unless in the cases mentioned. It is said that the disease has sometimes arisen under the influence of heat alone, and under circumstances where malarious emanations could not have operated, as in the case of vessels at sea. In general, however, where the disease prevails on shipboard, it is said to make its appearance when the vessels are approaching the land or entered into port, and it may be doubted whether heat alone, unconnected with malaria, is capable of producing it. Remittent fever, it is scarcely necessary to say, is especially a disease of warm climates. It is endemic in all the southern sections of Europe and Asia,—being especially violent within the tropics. It is far, however, from being equally prevalent in all sections of these countries. In Europe it is especially rife and severe in the south of Italy and some other portions of the Mediterranean coast, but it also prevails at times with severity in sections much farther north, where the character of the soil and other circumstances are favourable to the production of malaria, as in Hungary and the Netherlands.

Of tropical countries, certain portions of the East Indies, as the Delta of the Ganges, and the western and central section of Africa, are subject to the most destructive forms of the disease. In our own country it prevails most severely in its southern section and in the neighbouring islands of the West Indies. In general it diminishes in severity as you proceed northward, but in the northern section of the western States, on the borders of the great lakes, it is more prevalent than on the atlantic coast, in corresponding latitudes. The New England States, indeed, are in great measure exempt from it, whilst farther west, in the neighbourhood of the lakes just mentioned, it often prevails with great severity, and assumes, I believe, frequently, more or less of the congestive form.

The causes of remittent are chiefly operative during the summer and autumnal months. In this neighbourhood it is almost exclusively met with during the months of August, September and October. Besides climate and season, the various circumstances of moisture and dryness, the character of the soil, its elevation, &c. are powerfully influential, as already mentioned when speaking of malaria, under the head of intermittents. Besides these various conditions, however, there is at times a wide spread epidemic influence, such as prevailed a few years since in the United States, the causes of which are not understood.

As regards individual constitution, it is well known that persons long resident in a malarious district are less liable to be attacked than strangers,—men also are more frequently the subjects of it than women, but there is no proof that this is owing to any greater susceptibility, but only to greater exposure to the causes of the disease.

Great fatigue, exposure to the heat of the sun, or to cold and wet, &c. may operate as exciting causes, but only, I believe, where there has been previous or simultaneous exposure to the terrestrial emanations which we call malaria.

*Post-mortem appearances.*—The morbid anatomy of remittent has been much less extensively and carefully investigated than that of typhoid fever. This no doubt is chiefly owing to the fact already mentioned, that remittent fever is so little known in those places which have been the principal seats of modern investigation on this subject. For our knowledge indeed of the morbid anatomy of remittent, we are chiefly indebted to French or English practitioners, who have been temporarily located in districts where the disease has prevailed. It is not to be wondered at, therefore, if their descriptions are often far from being minute. Moreover, it is to be recollected that, with few exceptions, these investigations, although comparatively recent, were made at a time, when our acquaintance with morbid anatomy generally, and particularly the lesions met with in fevers, was much less satisfactory than at the present time. It is, therefore, sufficiently evident why many points in reference to the morbid appearances, cannot be stated with the completeness and precision which would be desirable.

As regards external appearances, yellowness of the surface and livid blotches are often met with. If death takes place early, the yellow tinge is slight, but if at a later period, it is deeper and more general.

The brain is sometimes spoken of as being inflamed, its vessels turgid, with effusion beneath the arachnoid or into the ventricles; but it may be fairly questioned whether the appearances here referred to were for the most part of much importance, or such as would at all warrant the inference of inflammation. At all events, it is now well understood, that appearances of a probably similar character, are met with in continued fevers and other affections, both where the functions of the organ were disordered during life and where they were not, and that such appearances are to be regarded as pseudo-morbid, connected often with the mode of death, or the mere result of the last agony, and not at all to be looked upon as evidences of any serious disease of the organ having existed during life.

In the cavity of the chest are sometimes found engorgement of the lungs, serous effusion in the pleura, flabbiness of the heart, its lining membrane stained of a deep violet colour, &c.—Some of these lesions must be considered in part at least

cadaveric, whilst the whole of them are strictly secondary in their character, and for the most part the product of the last stages of the disease.

It is in the abdomen that the most important lesions have been found. The spleen is commonly described as enlarged and softened; the liver as engorged with blood, enlarged, softened, and generally of a dark colour; the stomach as the frequent seat of inflammation. Other lesions are met with, but of their relative frequency and importance, it is impossible to form an opinion, from the very loose and general way in which they are noticed.

Such is a condensed summary of the principal appearances spoken of by different writers. I shall now proceed to lay before the reader, an outline of what I have met with in my examinations at the Pennsylvania Hospital, a detailed description of which was given in the paper before referred to.

The brain was found to be the seat merely of such alterations as are common to all acute diseases, its lesions being slight and comparatively unimportant.

The same is true of the lungs, which presented nothing particularly remarkable, except in a single instance where they were highly congested, their colour throughout being nearly black. The heart was frequently flabby, and its lining membrane of a deep red or violet colour, a condition often met with in other acute diseases. The stomach presented evident marks of inflammation in every case except one, and there was also a remarkable development of the glands of Brunner in the duodenum, in every case where the organ was particularly described; but the rest of the intestinal canal presented no important lesion except in two cases, in one of which the mucous membrane of the small intestine was softened and thickened; and in the other, that of the large intestine was softened and ulcerated, with thickening of the sub-mucous and muscular tissues. In the latter, dysentery was a prominent complication, whilst in the former the disease was protracted, and towards the close accompanied by diarrhœa. The liver was frequently enlarged, and its consistence generally diminished; but the most remarkable alteration was one of colour, which was met with in every instance. This colour more or less resembled bronze, or a mixture of bronze and olive, or some shades of lead colour. In describing the liver in the paper referred to, I have remarked that the most correct idea of the colour just mentioned, "would perhaps be conveyed by stating its predominant character, the same in every case, to be a mixture of gray and olive, the natural reddish brown being nearly extinct, or only faintly to be traced. This alteration existed uniformly or nearly so throughout the whole extent of the organ, except in a single instance, where a part of the left lobe was of the natural reddish brown hue. As the alteration of the colour pervaded both substances, the two were frequently blended together, and the aspect of the cut surface remarkably uniform. In one case, however, there was a marked distinction of colour, the olive being predominant in the parenchyma, the brown in the acini." In several cases where the disease had been protracted, the cut surface instead of the remarkable smoothness which it frequently presented, was more or less rough from hypertrophy of the lighter coloured substance (commencing cirrhosis). The bile in the gall-bladder was commonly abundant and perfectly fluid. The spleen was enlarged and softened in every instance, and generally to a great degree. The state of the intestinal canal and the development of the glands of Brunner in the duodenum, has been already mentioned. In one case, also, these isolated follicles were unusually developed throughout the whole of the small intestine, and in another in the last two feet of the ileum. The glands of Peyer were healthy in every instance. The mesenteric glands also were healthy wherever their condition is noted. In the paper already referred to, I have remarked that of the above lesions, "two only were constant or observed in every case, viz. that of the spleen and the peculiar alteration of the liver. We might perhaps include among the constant lesions, the development of the glands of Brunner in the duodenum, but it may admit of doubt whether these glands were really morbidly enlarged in every case, although at the same time, their frequent enlargement and uniform distinctness, constitute a striking peculiarity of the disease. Of those which were not

constant, the inflammation of the stomach is unquestionably the most worthy of attention, both on account of its great frequency and the importance of the organ itself. The lesion of the spleen, though constant, was similar in appearance to that found in other diseases. It was remarkable, however, for the uniformly great degree to which it was carried, and for being frequently accompanied during life with pain on pressure in the left hypochondrium, a circumstance not usually accompanying enlargement and softening of the organ in other acute affections. The liver, on the other hand, was the seat of a morbid change, not only present in every case, but of a character not met with in other diseases; and as it was the only lesion which afforded these two conditions, the conclusion is obvious that it constituted the essential anatomical characteristic of the disease, as it presented itself to our observation. As the number of cases was small, such a conclusion, when viewed as a general proposition, applicable to remittent fever universally, can only be regarded as the indication of a probable truth, the full confirmation of which requires the analysis of a more extended series of observations, conducted after the same manner." The probability, however, of its proving generally true, was increased by considering that the cases, although few, occurred in different seasons, and originated in different and widely separated places. Neither were they limited to any particular form of the disease, for some were of the pernicious character, whilst others were highly bilious, and others again of a more benignant form. The correctness of this view has been to a certain extent confirmed by subsequent observations which I shall presently refer to. Of the nature of the lesion in question, but little can be said. That it is inflammation will scarcely be contended by any one who does not make use of the term as synonymous with morbid action. As for congestion, its effect would be to produce a deeper red, not to destroy this tint. If infiltration of bile be appealed to, we must at the same time admit a peculiar alteration of this fluid and of the liver, inasmuch as the peculiar appearance here presented, is not met with in other diseases. In speaking of other diseases, however, I do not mean to include intermittent fever, which in its mode of origin and other features is so analogous to remittent, that, with Dr. Elliotson, I regard them as essentially identical. Since the publication of my paper, in which, besides my own cases, is mentioned one which occurred under the charge of my friend, Dr. Gerhard, at the Blockley Hospital, and where the liver, which was submitted to my inspection, presented the same characters, I have met with but one fatal case. This occurred at the Pennsylvania Hospital, in the fall of 1842, was rather obscure as well as mild in character, and proved fatal only by the supervention of pneumonia of the lower lobe of the left lung, which was found hepatized throughout nearly its whole extent. The liver offered the characters above mentioned, the spleen was enlarged and very much softened, the stomach without evident marks of inflammation, the rest of the intestinal canal presenting nothing worthy of note, the glands of Peyer healthy.

Recently I have been highly gratified at receiving through Dr. Stillé, of this city, a communication from Dr. Power, of Baltimore, in which the above observations are confirmed. Dr. Power is the attending physician to the Baltimore Alms-house, where in the fall of 1841, he met with three fatal cases of the disease. In all these cases the liver was large, softened or friable, and without sanguineous engorgement. The colour in one case is described as grayish-olive, which was uniform throughout, the two substances being confounded together; in another as slaty bronze, the two substances not being distinguishable; whilst in the third it was of a uniform dark slaty-gray hue. The spleen in every case also was enlarged and softened. In one case there was evident inflammation of the stomach as well as of the duodenum, which last was thickly sprinkled with enlarged mucous crypts, the rest of the intestinal canal as well as the mesenteric glands being nearly or quite healthy, the glands of Peyer scarcely distinguishable. In the other two, although the examinations were made severally 28 and 20 hours after death, putrefaction was so far advanced that the mucous membranes could not be satisfactorily examined. In one of these, however, it is mentioned that the glands of Peyer were neither ulcerated

nor enlarged, whilst in the upper part of the jejunum the glands of Brunner were hypertrophied. The above is a summary of the principal post-mortem appearances met with by Dr. Power. I have made it out from the more detailed account which he so kindly placed at my disposal, and at the conclusion of which he further mentions that at the same time he had met with two other fatal cases of remittent, one in town, the other in the service of his colleague Dr. Annan. "In both," he says, "the slaty bronze colour of the liver was marked; the organ was also enlarged, and its uniform hue, its friability, its strange appearance, so different from what I have met with in other diseases, dispose me to think, that this lesion is constant in remittent fever." He also observes that to his mind, these cases "bear out Dr. Stewardson's views as to the pathological lesion in this disease." Before leaving this part of the subject, I wish to call attention to the fact noted by Dr. Power in all his cases, viz., the absence of sanguine engorgement of the liver. That the peculiar lesion of the organ is not dependent upon sanguine congestion is sufficiently evident, but that this congestion was not even a concomitant, I had only alluded to as probable in the paper already mentioned, for indeed, I felt doubtful whether I had observed this point with sufficient attention to justify me in speaking with positiveness, in the face of the statement often made by those who have mentioned the condition of the liver in remittent, viz., that it is commonly engorged with blood. The observations of Dr. Power, however, confirm me strongly in my impression that this is questionable, especially as I can readily conceive that the enlargement, softening, and dark colour of the organ, might easily be passed by as evidences of sanguine engorgement, where the attention of the observer was not particularly directed to the distinction, and especially where the idea of congestion was previously present to his mind. This, however, as well as many other points, must be left to the determination of future observers, for however valuable the writings of former times, and however important their study in reference to those features of disease, to which in the then state of knowledge the minds of their authors were particularly directed, it cannot be supposed that by their perusal we could arrive at any thing more than the merest presumption upon many points which are either not noted at all, or in a very loose and general way. Before concluding the account of the morbid changes, it should be mentioned that from the thinness of the blood, and the absence of large firm fibrinous coagula in the heart after death, we may presume that its condition is in some respects analogous to what is met with in other fevers, but very different from that found in inflammations.

*Nature of the disease.*—This subject need not detain us long. It is scarcely necessary at the present day to remark that the phenomena of the disease cannot be traced to gastro-enteritis alone or combined with engorgement of the spleen, for the plain reason that these lesions are often met with where no such phenomena are present. It is equally clear, that in the present state of our knowledge at least, we cannot regard them as consequent upon the lesion of the liver, and hence we are forced to look for the essential element of the malady in some other portion of the economy. By some this is supposed to consist in a peculiar disorder of innervation, the traces of which in the nervous structure are not cognizable by the knife, and by others in congestion of the capillaries. A morbid condition of the blood has also been appealed to as the grand source of the malady; but all these views are more or less hypothetical, and incapable of any thing approaching to demonstration. It is something, however, to know what the disease is not; to have escaped the error of supposing that we have reached the source of the morbid phenomena, where in fact we are profoundly ignorant of it. Under such circumstances we are contented to accept such a partial theory as facts will warrant, leaving its complete development to a future period, when the progress of science shall have supplied us with more ample data. At present, then, it seems to me that all we can assert with safety is, that the sensible effects of the malarious influence, whatever it may be, are chiefly displayed in the disorder of the liver, spleen, stomach and duodenum, for these are the only organs which after death are found either

uniformly or very generally to present distinct evidences of organic derangement, and during life many of the most prominent and characteristic symptoms can be traced to them, such as the epigastric distress and tenderness, as well as that of the hypochondriæ, the præcordial anxiety and oppression, the bilious vomiting, &c., as also the more remote consequences of the hepatic lesion, viz., the yellowness of the conjunctiva, the sallow or yellow hue of the complexion, &c.

The predominance of the gastro-hepatic symptoms in the severe forms of remittent, especially in hot climates, has generally attracted the attention of observers; but this general statement requires the enlargement and precision which more recent investigations have given to it, before it can assume the importance which I think it deserves. It is quite one thing to speak of an organ as being the frequent seat of local determination in a given disease, and quite another to regard that organ as of necessity the seat of a certain form of morbid action, of greater or less severity, wherever the disease is present. Thus in typhoid fever we have a certain lesion of the glands of Peyer always present, whether the abdominal symptoms be severe or slight, and this lesion bears a totally different relation to the affection, from those local determinations which are common to all acute febrile affections, but universally present in none. In smallpox we have a pustular eruption upon the skin extending to the fauces and sometimes to the larynx. This lesion may be so severe as to give rise to the most horrid symptoms, or so slight as scarcely to occasion annoyance, but in any case it is present and forms a part of the disease, and nobody would think of regarding it, or the inflammation of the skin, fauces or larynx to which it might give rise, in the same light with the secondary local determinations above mentioned. To my mind, however, this would be just as reasonable as in the instance of typhoid fever to place the lesion of the glands of Peyer on the same level with mere local congestions and inflammations of variable seat. The first is essential, the latter accidental; the first is intimately associated with the peculiar morbid action which constitutes the disease; the latter belong to it principally as it is a disturbance of the circulation, and hence are common to all acute febrile affections. Some authors, however, will admit no such distinction, and place all the lesions found in fever upon the same level, so far as the point in question is concerned. For myself, I cannot so view it, and as regards remittent fever, I am disposed, for the reason, mentioned in the previous section, to regard the lesion of the liver which I have described, as belonging to the class of essential lesions. That of the spleen also is to be viewed in somewhat the same light, but as enlargement and softening of the organ exist in other diseases, this lesion cannot be regarded as strictly characteristic. The stomach, too, is so generally inflamed, as well as the glands of Brunner in the duodenum enlarged, that we must look upon these also as being more intimately associated with the affection than ordinary local determinations. As regards the morbid appearances found in the other organs after death, whether viewed in reference to their character or comparative frequency, they reveal only such local disorders as are common to all fevers. It is to these last, only, in my estimation, that we can consider as strictly applicable the remark often made by writers, that under different circumstances of climate, season, &c. we find the lesions of different organs predominating. Those lesions which are essential, may vary in severity indeed, but must always be present; they cannot, like the former, be present at one time or in one place, and not in another. This distinction between essential and accidental lesions, is one which is absolutely imperative in the present stage of scientific investigation, and one which should constantly be kept in view. So much for the organic alterations observed in remittent fever, and their relative value. But it must be recollected that whilst a number of the prominent symptoms are to be traced to the chief of these, they will not account for the whole train of phenomena. We must admit that there is something beyond, not cognizable by the knife, and which has hitherto eluded our research; something more general, be it a disorder of the nervous system, of the blood, or of any other portion of the economy. Upon this unknown element, essentially the same in all probability with that which is present in intermittent, we may presume

that the paroxysmal feature of the disease more directly depends, and that the curative influence of quinine, so controlling an agent in both affections, is especially directed. Whether the grand difference between intermittents and remittents consists in some modification of this element, or in the supervention in remittent, of local disease not present in intermittent, is not easy to determine. The first supposition, I think most probable; for although at first sight it seems very natural to suppose, that remittents are formed out of intermittents by the supervention of an inflammation, most probably of the stomach, by which the intermissions are more or less obscured, this idea does not seem to be borne out by post-mortem investigation. It is true that ordinary intermittents rarely prove fatal in the acute period, but so far as the point can be determined by a reference to what occurs in malignant intermittents, it would seem that gastritis is a frequent accompaniment of both diseases, and that the other local lesions, certainly that of the spleen, are much the same in the two affections. Of course I do not speak of the precise alteration of the liver which I have myself described, for whether this is present in intermittent as well as remittent, or uniformly present in either, can only be determined by future observation, now that attention is directed to the subject. It seems probable then that remittent differs from intermittent, not in the supervention of a local affection not belonging to the latter, but in some modification of the more general element above spoken of, which constitutes the great substratum of the disease.

*Diagnosis.*—From intermittent fever, remittent can be distinguished only by the circumstance of the intermission which occurs in the former. In other respects they are similar, and as it is sometimes difficult to say whether an intermission is perfect or not, the distinction between the two affections is at times more or less arbitrary. Not so, however, with the diagnosis between remittent and continued fevers, understanding by the latter those fevers which are uniformly and essentially continued, such as typhoid and typhus fever. We say uniformly and essentially, because in remittent fever, the remissions may at times become so obscure as to give to it more or less of a continued form, but this continuity, so to speak, is accidental, and rarely if ever so complete but the sagacious observer will be able to detect the evidences of its remittent basis, at least in some part of its course. When the remissions, however, become thus obscure, the disease is said to pass into the continued form, and this in one sense is true; but it is to be feared that many physicians are, from the use of this mode of expression, insensibly led to regard the disease as then really identical with proper continued fever. This is a great error, and to avoid such confusion it would be better to designate this state as pseudo-continued. The term remittent is applied to the disease before us, as expressing one of its general characteristic features, but then it is to be recollected that this is not the only one which distinguishes it from those fevers technically styled continued. Whether, then, the remittent type be so distinct as to approach to the intermittent, or so obscure that the fever becomes pseudo-continued, the disease is still technically remittent, its essence remains the same, its other characteristic features still persist. To these features we shall now allude; and first as regards the cerebral functions: In the benignant and even some of the more malignant varieties of remittent, the intelligence is comparatively sound, the senses perfect, and the answers prompt, whilst in others, especially those partaking more or less of the pernicious character, there may be violent phrenitis or profound coma; but the suddenness, the severity, and, unless where soon followed by death, the comparatively rapid abatement or even the entire disappearance of these symptoms in a very short time by the occurrence of a complete remission, sufficiently distinguish them from the constant and progressively increasing wandering, dulness, delirium and stupor of typhoid or typhus fever, accompanied as they are, each by a peculiar expression and a dingy redness of complexion which does not belong to remittent, in which, on the contrary, there is more commonly sallowness, or lividity, or yellowness of surface. Besides the difference of hue, the former are accompanied by an eruption of a few rose-coloured spots upon the trunk in one case, and of a more extensive and deeper coloured efflorescence in the other, neither of

which are met with in remittent. In the latter, the thoracic organs suffer but little, whilst in typhoid fever, there is frequent bronchial irritation, and in general a greater tendency to inflammation of the lungs themselves. Great oppression of the respiration seems more common in remittent, but this is probably in great measure owing to the state of the abdominal viscera, of the symptoms of which we will now speak. To say nothing of costiveness in remittent, as contrasted with diarrhoea in typhoid fever, it is here especially important to observe that the presence of early bilious vomiting, of hypochondriac tension and soreness, of epigastric distress and anxiety, which in cases of extreme severity become perfectly intolerable, accompanied by the most deadly sickness and constant retching, are positive phenomena highly characteristic of remittent when compared with either typhus or typhoid fever. On some of these M. Littré has laid particular stress, in his admirable essay introductory to the epidemics of Hippocrates, where he has most successfully established the opinion previously maintained, but never fully proved and carried out by some of the English writers, that the fevers observed by Hippocrates were to be classed with the remittents of hot climates, and entirely different from the continued fevers of temperate climates, especially of Paris, where typhoid fever prevails almost exclusively. Thus he finds, upon examining the cases recorded by Hippocrates, that this great observer has noted the presence of swelling, or tension, or pain of the hypochondria, in about one-third of them, a result exactly in accordance with that obtained by an analysis of the cases reported by Twining in his account of the fevers of Bengal. On examining, however, the cases of fever at Paris reported by Petit and others, a very different result is attained, for here the hypochondria are scarcely ever the seat of any notable symptoms. Hence M. Littré concludes that the condition of the hypochondria in the former is remarkably characteristic; for, says he, it indicates a *peculiar lesion*. Besides the features already mentioned, we should notice the rapid course of remittent, proving fatal, as it sometimes does, in a very few days, and consequently the early presence of certain symptoms, in cases where they are met with at all, such for instance as dryness of the tongue, all which is in marked contrast to what is met with in either typhoid or typhus fever. In connection with the paroxysmal character of remittent, we of course often have free perspiration, cool surface, &c., in the remission, or chilliness preceding the exacerbations, but in pernicious remittent the tendency to coldness becomes extreme, being accompanied by cold sweats and livid extremities, thus constituting another remarkable feature of remittent when compared with typhoid or typhus fever.

If from a consideration of the symptoms, we turn to the post-mortem appearances, we find equally striking differences, remarkably in accordance with those met with in the former. For instead of the diseased condition of the liver, spleen, stomach and duodenum, already so fully described as belonging to remittent, accompanied as they are by a comparatively healthy condition of the rest of the alimentary canal, we find nearly the reverse true of typhoid fever, in which the liver is commonly healthy, or nearly so; the mucous membrane of the stomach equally, if not more frequently healthy than in the generality of acute diseases of all descriptions; the spleen presenting, indeed, evidences of engorgement, which, however, from the absence of pain and uneasiness in that region during life, must evidently be of a more passive character than that belonging to remittent; whilst in all cases, the glands of Peyer, in the lower portion of the small intestines, are found to be the seat of a peculiar lesion not met with in remittent fever, or any other disease. As regards typhus fever, no characteristic lesion has yet been found; all the alterations hitherto met with being such as are common to other acute diseases.

Now, if we reflect upon the above differences in symptoms and post-mortem appearances, and, at the same time, call to mind the differences in the mode of origin, prevalence, &c., as well as the different terminations of these fevers, we cannot fail to recognize the fact, that remittent fever, however it may assume a pseudo-continued form, is at all times essentially distinct from typhoid or typhus fever. This is important to observe, on various accounts. It is important in practice, that

we may avoid the error of supposing, that in proportion as the fever becomes more continued by the remissions becoming more obscure, it really assumes the nature of what is technically called continued fever. It is of the last importance, too, in discussions on the subject of fever, and in comparing the writings of different observers. It is for want of making this distinction, as M. Littré has shown, that the epidemics of Hippocrates have been so imperfectly appreciated in modern times. How, indeed, could this be otherwise, when we reflect, that the Hippocratic views of fever were based upon the observation of a disease scarcely known, except by the accounts of travellers, in the great modern European schools, whose views of fever, on the other hand, were based upon the observation of quite a different affection. So long, therefore, as what we meet with in the latter, was made the test of the value of the views of Hippocrates on the subject of fever, his writings could but be misinterpreted and his observations be unjustly appreciated. To be understood, his "*epidemics*" must be studied under the conviction that they belong to the history of remittents, of the course, symptoms and prognosis of which, in the opinion of M. Littré, they may still be regarded as containing one of the best accounts which we possess. We cannot help remarking how admirably enlarged and philosophical is the spirit with which this gentleman has conducted his examination of these writings, comparing what is therein contained with the results of modern and coteremporary investigation, with a view to mutual illustration and support, a spirit so delightfully in contrast with that narrow-minded and jealous disposition, which seems especially to delight in discovering only such notices in the older writers as can be turned, however unjustly, to the disparagement of more recent observations.

We have extended our remarks on this subject, mainly with the view of enforcing the importance of making a proper and just distinction between the fevers mentioned. Practically, however, in the great mass of cases there is little difficulty in the diagnosis. It is chiefly, I believe, in the milder form of remittent in rather temperate climates, where the remissions may happen to be indistinct, that the difficulty of diagnosis between it and typhoid fever chiefly arises. The presence, however, of the chief phenomena of remittent already alluded to, even though not strongly marked, together with the absence of the characteristics of typhoid fever, cannot, in general, long leave the well instructed practitioner in doubt. Severe bilious remittents appear often to be confounded with yellow fever, but of the distinction between these we shall speak when treating of the latter.

*Treatment.*—In cases where the inflammatory excitement is moderate, and unaccompanied by severe local symptoms, the use of a mild cathartic, with rest, low diet, and the common adjuvants of an antiphlogistic course, are all that is necessary to bring the disease to a favourable termination. Not so, however, in its more severe forms; and here we have first to consider the propriety of employing the lancet. In those cases where the inflammatory excitement runs high, especially when accompanied by strong local determinations, it cannot be questioned that free bleeding at the commencement is not only proper, but imperatively demanded, and usually followed by the most prompt relief. When, however, a greater softness of the pulse and other circumstances indicate a different condition of the system, bleeding, although it may still be proper, should be cautiously employed. It is said by Twining, in his account of the fever in Bengal, that the loss of blood at the commencement of the first or second paroxysm in severe cases of remittent, is almost always useful. At a later period, however, unless its use is indicated by a high degree of arterial action, or distinct evidences of local inflammation, he says that it is of doubtful value; whilst in the more advanced stages, if it becomes necessary to resort to it, the patient should be carefully watched, in order that its injurious effects may be promptly met by the use of quinine and other means. Besides the stage of the disorder, great stress is laid by the same author upon the period with reference to each febrile exacerbation, when blood should be drawn. When the paroxysm is on the decline, the pulse becoming soft, and the skin in a state of perspiration, the loss of blood is no longer admissible for the time,

because of the approaching stage of collapse and prostration. He has even known some cases in which local depletion, accidentally delayed to this period, has been followed by fatal results. Of course it is only in severe cases where the tendency to prostration is great, that such extreme consequences would be met with, but still in milder cases the effects might be injurious. As a general rule, then, it may be stated that venesection is highly advantageous when resorted to during the first few days after the attack, especially when the disease is highly inflammatory. Not only is it followed by the immediate good effects of a more rapid solution of the paroxysm and complete remission, but permanent visceral obstructions and alterations are less likely to supervene at a later period. Where the signs are rather those of oppression, caution, of course, is to be observed; the effects of the operation carefully watched, and its happy influence promoted by the use of counter-irritants. In a disease of such varied character, whether from climate, season, locality, or other cause, only the most general rules of practice can be laid down, and hence as regards the propriety and extent of depletion, the practitioner must be greatly influenced by what experience has taught him in reference to its safety and advantage in a particular epidemic, locality, &c.: as a general rule it is safer in a dry than a humid climate, and amongst those who have recently arrived from a more northern climate, it is better borne than by the natives of hot climates.

*Emetics.*—Experience seems now decidedly opposed to their employment. They are apt to bring on or aggravate gastric irritability, followed perhaps by evidences of more general intestinal irritation, watery discharges, &c., and also to render the course of the disease more prolonged and the remissions less distinct. The practitioner should not be misled by the momentary relief which may follow the administration of an emetic, especially when given in the decline of the paroxysm, the relief being really attributable perhaps to the natural remission, and followed by tenfold aggravation in the succeeding exacerbation. However, even supposing that emetics are occasionally beneficial, it is scarcely to be doubted that they are more commonly injurious, the sickness of stomach being aggravated, and the vomiting sometimes rendered constant and uncontrollable. Still in some cases it may be desirable to evacuate the stomach at the outset, and if so we should resort to the mildest measures, as a draught of chamomile tea, or the like, to the complete exclusion of antimonial or other irritating emetics.

Of the propriety of freely evacuating the bowels by a mild cathartic, there can be no question. In ordinary cases, epsom salts alone or combined with magnesia will answer every purpose; or a few grains of calomel followed by a saline cathartic may be employed. Irritating cathartics should be avoided, or at least, if occasionally demanded, they should not be persevered in, as they would be liable to aggravate the morbid condition, by inducing intestinal irritation, thin acrid discharges, tormina and tenesmus. It is scarcely necessary to observe that when the stomach is very irritable, we should endeavour to allay this condition by the effervescing draught, iced cold drinks and other usual remedies, before giving a purgative, the administration of which, under such circumstances especially, is better deferred until the remission, when not only the gastric disturbance, but the general excitement, has more or less subsided. Where, for the time, cathartics cannot be administered by the mouth, and it is desirable promptly to evacuate the bowels, enemata of course should be resorted to.

Such is the plan of treatment usually requisite in the early stage of most remittents. At the same time the patient should be kept in a state of repose, his apartment freely ventilated, his face and arms sponged with cool water when the skin is hot, and all the usual adjuvants of an antiphlogistic course resorted to as occasion may require. As the case advances, unless where remedial means are called for to counteract local determinations, or where symptoms of prostration should rapidly supervene, little more is requisite than to confine the patient to bland mucilaginous or farinaceous articles of diet, and administer such mild remedies as may be calculated to promote gentle diaphoresis and keep the bowels freely open, without occasioning too frequent discharges. A free use of citrate of potash or some similar

article, will often answer both these indications, and is eminently serviceable; or it may be necessary to make use in addition of some mild laxative from time to time. In addition to the means already mentioned, however, it should be observed that by some it is recommended to administer calomel freely during the first few days, until the system is moderately brought under its influence. As regards the ordinary remittents of this section of country, such a practice is, I am satisfied, altogether unnecessary, and sometimes, at least, injurious. It would be unwise, however, to infer from hence that under other circumstances, and especially in warmer climates, the practice of resorting to large and oft-repeated doses of calomel is not called for. This point, we conceive, remains to be settled by the careful observations of enlightened practitioners under the circumstances mentioned. It should be recollected, however, that such practice, if proper at all, is so only in the early stage, and that strong mercurialization or ptyalism is at all times to be avoided.

One of the most important points of treatment in the progress of remittent, is to attend to the local affections. According to our own observation, there is very generally in the course of the disease more or less tenderness of the epigastric or hypochondriac regions, especially the left. Even where this soreness is not great, and is accompanied with but slight sensations of uneasiness or oppression, it is often serviceable to detract a few ounces of blood from the part, by cups or leeches. It not only relieves the local uneasiness, but is most efficacious at this stage in bringing on a complete remission, and thus favouring the solution of the disease. Frequently, however, the tenderness, pain, and other associated symptoms are so severe, as imperatively to demand local depletion with a view to their relief. This measure is most serviceable and especially called for during the exacerbation, when the epigastric or hypochondriac pain and tenderness is most marked. Not only so, indeed, but it is also necessary to be cautious even in the local abstraction of blood, in those forms of the disease where sudden prostration is to be dreaded, that we do not resort to it when the remission is about taking place. Topical depletion to the epigastric or hypochondriac regions should be repeated during the successive exacerbations as long as there is much local uneasiness and the state of the pulse will admit of it. In conjunction with this practice, it may be desirable to keep up a decided action upon the bowels, and for this purpose, small doses of blue pill and rhubarb, to be repeated every few hours, may be advantageously resorted to in addition to the saline draughts, &c. already mentioned. Before leaving the subject of the local abstraction of blood from the epigastric and hypochondriac regions, we should observe that this measure is important not merely for its immediate effects, but with a view to prevent those chronic alterations of the spleen and liver, which when firmly rooted are so obstinate in character and sometimes fatal in their ultimate result. The condition of these organs should also be kept in view in those cases which become protracted, with slight fever or rather febricula, imperfect remissions, emaciation, dryness of tongue, &c. Here it will often be found that inflammatory engorgement of the spleen, or subacute inflammation of the stomach or neighbouring parts, is the grand source of difficulty, and that the local abstraction of blood, a bland diet, the omission of tonics, if they had been previously resorted to, and the use of a small portion of opium or Dover's powder to allay irritation, &c. will bring about a most happy change.

Local depletion to the temples or back of the neck is often needed during the exacerbation, to relieve the determination of blood to the head. Where stupor or coma supervenes in the course of remittent, the same remedy is called for where the pulse will admit of it, in conjunction with a brisk cathartic, and the prompt application of a large blister to the back of the neck, if the symptom does not quickly give way.

Besides the local affections already mentioned, various accidental complications may arise, which must be met by the usual remedies. The same may be said of the general system, which, as in other febrile affections, may call for the use of small doses of blue-pill, ipecacuanha and opium, for instance, where the tongue

becomes dry and brown, or of the various stimulants, such as carb. of ammonia, camphor or the like, where the powers of life fail. There still remains, however, an important feature in the treatment of remittent, which has not yet been noticed; we mean the use of bark or its preparations.

On the propriety of having recourse to cinchona in this disease, there has been much difference of opinion among medical men. Some advocate its use as soon as the remission has declared itself, whilst others strenuously condemn it. Such difference of opinion can hardly be accounted for, without supposing that the effects of the remedy are very different in different forms of the disease, and in different years and climates. Thus in the fall of 1839, in the neighbourhood of Philadelphia, the disease, after a few days of preliminary treatment, was marked by very perfect remissions, and was then promptly controlled by quinine, the effect of which in other years has been far from being so happy, at least until a later period of its course.\* There can be no doubt also that in the great majority of cases, the disease, after a certain duration, will arrive at a favourable conclusion without the use of bark or quinine, which, on the contrary, may be productive of injury if injudiciously resorted to. On the other hand, it seems equally clear that there are cases, in which this remedy is our grand resource, and where without it, a fatal result would almost necessarily follow; whilst at the same time there are many more, where if judiciously employed, it is of very important advantage. It must also be recollected that objections formerly made to crude bark may no longer apply to quinine, which is much less likely to disagree with the stomach and bowels, or occasion any general irritation of the system, whilst at the same time it may be administered in vastly more effective doses. As a general rule it may be stated, that in proportion as the disease is inflammatory with imperfect remissions, quinine is inapplicable, whilst on the other hand, the more it is characterized by softness of pulse, prostration, and especially by those symptoms which belong to pernicious remittents, the more this remedy is demanded. It should be given in the remission in large doses, from 5 to 10 grs., and repeated at short intervals previous to the ensuing exacerbation. In violent pernicious remittents, still larger doses may be called for, for here the life of the patient may depend upon the arrest or modification of the ensuing paroxysm. It is best given in solution, and may often be advantageously combined with sweet spirits of nitre or laudanum, or even with a stimulant, where the system requires to be roused. In these lethargic pernicious remittents, quinine is imperatively demanded, as well as in many which hold a middle rank between these and the pseudo-continued inflammatory remittents. Sometimes where inflammatory symptoms are present, they subside as the disease advances, and the remissions become distinct. Here again, quinine may be resorted to, and this leads us to the further observation, that it is almost always serviceable in the decline of the affection under any form, by rendering convalescence more firm and prompt, and by lessening the risk of its being converted into chronic intermittent. Of late years this remedy has been much employed in the United States as well as elsewhere, and it seems abundantly evident that it is capable of exercising over remittents a control very analogous to that which it does over intermittents, whilst at the same time it is less universally applicable, and is more often contra-indicated in the former than in the latter. Some of these contra-indications, we have endeavoured to point out, as well as the general conditions in which the remedy is most applicable. As regards its special applicability in particular cases, much must be left to the discrimination of the practitioner, aided perhaps by a cautious trial of its effects. All that I would insist on, is the general value of the remedy, as proved by numerous and competent observers, and of which my own experience has afforded me ample confirmation.

In conclusion, let us observe, that besides the differences of treatment dependent upon the multiplied varieties of form assumed by the disease, the practitioner should always keep in view its remitting tendency, since a remedy, like venesection, for instance, may be required at one moment, and yet be altogether inadmissible a few hours later, when a different medication may be demanded. These variations and

the probable period of their recurrence should be constantly kept in view in order to the proper regulation of the treatment. He should carefully attend to the evidences of local disorder, particularly in the epigastric and hypochondriac regions, recollecting that the force of the disease, so far as this becomes localized, appears to be mainly spent upon the organs there situated, and of course that it is highly important to moderate at once, by local depletion and other means, any excess of action which may be there displayed. Finally, he should recollect the special control exercised by quinine, and its importance and value, under the circumstances before mentioned. These are grand features of the treatment of remittent, which have no application to typhoid or typhus fever. To say, then, that the indications of treatment in remittent are much the same as in proper continued fever, is entirely erroneous. On the contrary, the very different indications which belong to the former, point out, like every other portion of its history, how radically distinct it is from the latter.

*Yellow Fever. (Dr. Stewardson.)*

At the present day it seems pretty well established that this disease must rank as a species of continued fever. In some of its symptoms, it is analogous to the severe forms of bilious remittent, and hence it has often been confounded with it, and regarded by some as a mere variety of the latter. Sound observers have not been wanting, however, from time to time, who, like Jackson in his account of the fevers of Jamaica, have appreciated with more or less clearness the distinction between these two affections. Accumulated evidence seems to me to have established this distinction, almost beyond doubt. By far the most important essay which has recently appeared, is that published by M. Louis, containing an account of his observations upon the disease, as it appeared at Gibraltar in the year 1828. Not only has he described its symptoms with remarkable accuracy, but also its morbid anatomy, whence he has been enabled to define its pathological characters with more precision than had previously been done. As in other acute affections, the symptoms may vary somewhat in different epidemics, but still they commonly present such uniformity of character, that the description of one epidemic affords a sufficiently accurate portraiture of the disease in general. M. Louis, in his general description of the fever of Gibraltar,<sup>a</sup> gives, *first*, the symptoms met with in the fatal cases; *secondly*, those of the severe cases which recovered; and *lastly*, those presented in the mild cases.

1st. In *fatal cases* the disease commenced at different periods of the twenty-four hours, usually with an intense headache, accompanied by chills, shivering, pain in the limbs, and soon after, pain in the back. A heat, rarely intense, succeeded to the chills, and was sometimes followed by perspiration. At the same time the countenance became red and animated; and in some cases, as it were, swollen. The eyes were red, glistening, suffused, and in many cases the patients complained of a sensation of smarting in them. The thirst was intense, the anorexy complete. The first symptoms, the headache, the pain in the limbs, the anorexy, the thirst, the heat, the redness and the pain in the eyes, continued, the headache during half the disease, the pains in the limbs a little longer, and the heat, which in many cases was but slightly increased, continued so during nearly the same time. The pain at the epigastrium, so rare at the commencement, came on usually fifteen or twenty hours later. It was generally inconsiderable, and very few patients complained of severe or acute pain. With the epigastric pain came the nausea and vomiting, excited by drinks and purgatives in several cases, spontaneous in others. The dejections were infrequent, that is, where no laxatives had been administered. The abdomen preserved its form, was supple and not painful to the touch, except in the epigastric region. The sleep was inconsiderable; some patients were restless, in some there was a good deal of jactitation during the night.

<sup>a</sup> Researches on the Yellow Fever at Gibraltar, by M. Louis, translated by Dr. Shattuck, Boston, 1839.

Others, and the smaller number, experienced as early as the third day, a real anxiety, could not remain quiet in any posture, and in some cases there was delirium. But this symptom did not usually come on till the last day of life, and for this reason it is to be considered rather as belonging to the agony than to the disease. Otherwise, with few exceptions, there was neither prostration nor stupor. The pulse was moderately accelerated, regular, generally bearing relation to the degree of heat, which was almost always slight, as I have before said. The skin of the thorax was injected in some cases. This redness, and that of the eyes, diminished towards the middle period of the disease, or a little later, and new symptoms appeared. To the injection of the integuments of the chest there succeeded a slight yellow tint of that part, and the eyes were of the same colour. When this colour appeared thirty-six or forty-eight hours before death, it became rapidly brighter, so as to be of some intensity at the time of the fatal termination. In other cases, where it came on only just before death, it was slight at the autopsy, and commonly limited to the trunk. At about the same period, or a little later, the matter vomited, from being of a yellow colour, became brown or black, and the dejections blackish or black. At the commencement of this change of colour, the vomit was of a liquid matter more or less grayish, mixed with a greater or less quantity of mucus; in which were to be seen blackish parcels, like soot. At this period of the disease, the uncomfortable feelings and the anxiety continued during different lengths of time and in different degrees, the strength diminished, the temperature fell, so that the limbs were cold before the agony; in some cases there was suppression of urine. Sometimes also a sort of remission or apparent amelioration of the symptoms was observed, and death took place when it would least have been expected, had not experience taught the practitioner to distrust this deceitful remission. In some subjects the violence of the headache, that of the pains in the limbs, the marked febrile symptoms, the numerous vomitings, the uncomfortable feelings, the anxiety, the bright redness of the eyes, gave to the disease a truly serious aspect, whilst in others the mildness of the fever and of the pains wherever seated, the absence of agitation and delirium, the slight diminution of the strength, impressed on the disease a character of mildness, calculated to deceive at once the patients, their attendants, and the physician. It is under this form of the disease, that patients died without taking to their beds, on foot, as it was expressed by their friends.

In the *severe cases which recovered*, the symptoms at the commencement were much the same as in the fatal cases. In a certain number, vomiting came on from the first to the third day. The epigastric pains were wanting in a greater number of cases; the pulse was moderately accelerated; the heat slightly increased. In some subjects, the stools became black towards the middle of the disease or a little later. The brown and black vomit occurred in the cases of a few individuals only, and these were mostly children. The redness of the eyes rarely increased after the first day, and on the contrary, gradually became less. Restlessness at this period was rare. The extreme restlessness, the jactitation, which took place in those who died, was not met with in the cases now under consideration. Yellowness was wanting in a great number of cases. Towards the fifth day, the symptoms became less severe; the skin became cooler; the pulse calm; the epigastric pain diminished or completely disappeared; the thirst was less; the appetite returned, and convalescence commenced. This was generally long, that is, in proportion to the duration of the disease, the mean duration of which was from seven to eight days. The strength was not perfectly re-established sooner than from ten to twenty days after the cessation of the febrile symptoms.

The *mild cases* differed from those just described, not only in the mildness, but also in the smaller number of the symptoms, and in the extremely short duration of the disease. The epigastric pains were rare, and so too were the vomitings, which were almost never spontaneous, and in no case of a brownish colour. The heat and thirst were moderate, and so slight was the diminution of the strength, that the patients did not keep their bed at all, or were there for half a day only,

thus, according to their expression, going through with the disease on foot. Here also the convalescence was long, longer even in proportion to the duration of the disease, than in the severe cases. A relapse was rare.

Such is the remarkably accurate description given by M. Louis of the epidemic of Gibraltar. In its principal features, it accords with the accounts of other writers. The grand characteristics of the affection appear to be nearly the same in all epidemics.

*Anatomical Characters.*—We shall first give an abstract of these as observed by M. Louis and described in the work already quoted. The brain was found to be the seat only of such slight alterations, as are met with more or less frequently in the most common acute diseases. In the spinal marrow likewise there were no appearances peculiar to yellow fever. Except in one respect, the same was true of the organs contained in the cavity of the chest. The pleuræ indeed were remarkable only for the absence of recent lesions of any importance, and the lungs were found hepatized in but a single instance, and then only in a space about equal to that of a hen's egg. But although inflammation of the pulmonary tissue was rare, exhalation of blood into it was frequent. This exhalation was marked by the presence of numerous black spots, or masses of the same colour, the latter containing no air, not granulated, without evident organization, usually easily broken, and in some cases yielding by pressure the blood of which they were almost entirely composed. The œsophagus was completely deprived of epidermis through its whole length in a third part of the cases, and partially so in a greater number. The stomach contained a clear or dark red coloured liquid, a blackish or a perfectly black fluid, in three-fourths of the cases. Its mucous membrane was very frequently inflamed, being natural as regards consistence, thickness, &c., in only one-fifth of the cases. The mucous membrane of the small intestine, presented unequivocal evidences of inflammation in but few cases, and the glands of Peyer, save a slight tumefaction of some of them in one case, that of a child, were perfectly healthy. It contained a greater or less quantity of reddish, brownish, blackish, or perfectly black matter in two-thirds of the cases. The same was found in the large intestine in nearly the same number. The liver was natural as regards size in nearly every case; it was firmer or more coherent than natural in a few cases, whilst in some others it was rather less so; its colour was altered in every case; sometimes it was of the colour of fresh butter, sometimes of a straw yellow, a clear coffee and milk colour, sometimes of a gum yellow, sometimes of an orange colour. This change of colour existed throughout the whole extent of the organ except in three cases, where the right lobe preserved its natural colour either in part or entirely. In the others, also, the discoloration was most marked and uniform in the left lobe. At the same time, there was a diminished quantity of blood, the sections being dry, where the discoloration was well marked. But little bile was found in the intestinal canal, and that contained in the gall-bladder was scanty, thick, and of a dark green colour. The spleen was natural in half the cases; in some it was a little enlarged, in others somewhat softened, but with one exception to a moderate degree only.

Of the lesions just described, two, viz. that of the liver, and the red or black matter found in the intestines, are peculiar to yellow fever; the others, common to it and other acute diseases. The alteration of the liver being not only peculiar to the disease, but present in every case, must of necessity, concludes M. Louis, be regarded as constituting its anatomical character. That the principal features of the above description are not peculiar to the Gibraltar epidemic, is sufficiently evident from observations since made in the West Indies and elsewhere. In a case which I had the opportunity of examining in the Pennsylvania Hospital, the appearances met with were remarkably similar to those just described.<sup>a</sup> It must be left, however, to future observation to determine, whether the alteration of the liver is constant under all circumstances, and hence properly to be regarded as the essential anatomical character of the disease. It cannot be questioned, however, that

<sup>a</sup> Amer. Journ. of Medical Sciences. January, 1842.

this condition is a very general and important feature in the post-mortem appearances. M. Catel says that in the epidemic of 1838-39, at St. Pierre, the liver was found pale and yellow in all the cases examined, which amounted to one hundred and fifty. The gall-bladder, also, was most frequently empty.

*Diagnosis and nature.*—It is evident that the disease as observed at Gibraltar, was a continued fever, and it may fairly be doubted whether it is ever characterized by regular and distinct remissions. Towards the third or fourth day, especially in the inflammatory form, there appears to be sometimes a rapid abatement of the more violent symptoms, the pulse falls, and the skin becomes cool. This abatement, however, is but the precursor of a favourable, but more commonly of a fatal termination, and not to be confounded with a true remission. It is also said, that shortly after the attack has commenced, in the course of the first twenty-four hours, the patient will express himself as feeling better, although the symptoms indicative of intense disorder still persist. "A trifling abatement of the symptoms," says Dr. R. Jackson, "was sometimes taken notice of, in ten or twelve hours after the commencement, but in no instance, so far as I have observed, was there ever so much alleviation, as with any justice could be called a remission." It is not unlikely that these changes, especially where the mind of the observer was already prepossessed with the idea that yellow and remitting fever were essentially the same affection, may have led to the supposition that the former presented a truly remitting character. That it ever does so, appears at least to be very doubtful.

In severe cases of yellow fever, the presence of black vomit and dejections, the yellowness, the extreme distress, combined with the rapid course of the disease, render it readily distinguishable from any other affection, if we except those violent and rapid forms of bilious remittent, which are accompanied by yellowness and extreme gastric distress, to which we shall presently refer. In some cases, however, the characteristic symptoms are wanting, and here a real difficulty may arise; so much so, indeed, that it may be impossible to arrive at any thing more than a probable conclusion, by taking into the account the circumstances of the attack, the prevalence or not of an epidemic at the time, and how far it is possible to account for the symptoms on any other supposition. Of course, in the few fatal cases, where doubts exist during life, these may be removed by a post-mortem examination, the presence of the black matter in the stomach and intestines, or the specific alteration of the liver, affording conclusive evidence.

We now proceed to consider the distinction between yellow fever and the severe bilious remittents, with which it may be confounded. In the former, as already remarked, the fever is generally, if not always, of the continued type; and hence this feature alone would be sufficient to settle the question, where we have an opportunity of carefully watching a case from the commencement. But unless other differences could be pointed out, it might be fairly questioned whether the two diseases were essentially distinct. In remittent, then, let us recollect, that the matter vomited is usually bilious throughout, whilst in yellow fever it is first clear, then yellowish, and finally blackish, or completely black. It is said also that in the latter the stomach is emptied without effort, and the desire to vomit ceases for the time, whilst in remittent the act of vomiting is painful and difficult, and the nausea persists. In remittent, there is a tendency to fulness of the hypochondriac and epigastric regions, whilst in yellow fever, according to Louis, the abdomen uniformly preserves its natural form. I cannot help thinking that this difference in the conformation of the upper part of the abdomen, will be found to be an important distinctive feature; but to determine the question requires further observation, and I therefore throw it out as probable merely. The probability is to my mind much increased by considering that in remittent the spleen and liver are, generally at least, enlarged, and often to a great degree, especially the former, whilst in yellow fever they preserve their natural size, or nearly so, and hence we should naturally expect a corresponding difference in the conformation, at least of the hypochondria. In remittent, also, the hypochondriæ, especially the left, are sometimes painful, a condition, so far as we are aware, not noticed in yellow fever. The character of the yellowness is said to be different in the two diseases; and Dr.

Stevens affirms that in yellow fever the patients do not shake nor tremble like those who are under the influence of marsh poison, and that the expression of countenance is so peculiar, that those who have once seen it, easily recognise it. R. Jackson, also, in his account of the fevers of Jamaica, says that the horror and shivering which so usually precede fevers, were seldom great in degree in the disease before us. Cramps, too, are said to be much more frequent in this than in remittent fever. Such appear to be the principal points of difference, so far as regards the symptoms; and if we consider them in connection with other differences presently to be mentioned in reference to the origin, prevalence, &c. of the two diseases, the very opposite condition of the liver and spleen, as discovered by post-mortem examinations, and the presence of a brown or black matter in the stomach and intestines in the one case, which is not met with in the other, it seems to me that it is scarcely possible to avoid the conclusion that the two diseases are essentially distinct. The enlargement and softening of the spleen in bilious remittent, and other types of fever of malarious origin, is a prominent fact attested by most writers; and this fact alone is almost sufficient to convince us that yellow fever, in which the spleen rarely presents any considerable traces of disease, must be essentially distinct in its nature. The very opposite conditions of the liver are also especially worthy of notice; that in yellow fever being anemic, with deficiency of bile in the gall-bladder,—that of remittent being usually enlarged, and with the gall-bladder fully distended. To this different condition of the liver and spleen in the two diseases we may probably refer for an explanation of another distinguishing feature in their history. I allude to the fact that in yellow fever the convalescence is complete, the supervention of chronic disorder being a rare circumstance, whilst in remittent fever it is very liable to arise, especially in the organs referred to. The rarity of chronic disorder as a consequence of yellow fever, is attested by M. Catel in his account of the disease as it prevailed at La Martinique in 1838-'39. Of more than a thousand patients in the hospital of Saint-Pierre who recovered, not a single one presented at the time of his discharge any evidence of disease which was likely to become chronic. Before dismissing the subject of diagnosis, we should mention that Dr. Stevens states that there is still another disease very similar to and often confounded with yellow fever, but really distinct, viz., the seasoning fever of the West Indies, the mere consequence of excessive heat in persons unaccustomed to the climate.

As regards the essential nature of yellow fever, we are entirely ignorant. The local lesions, however important or characteristic, are clearly insufficient to account for all the phenomena, in their origin and course. We cannot agree with those who would designate the disease, as has lately been done by M. Catel, as a gastro-entero-cephalitis, for the plain and sufficient reason that gastro-enteritis is a condition constantly met with, but characterized by phenomena very different from those of yellow fever, and that if we invoke cephalitis in addition, we are no nearer an explanation of the peculiarities of the disease, whilst at the same time we are assuming what is not true, at least in a large proportion of cases. But although in the present state of our knowledge, we cannot arrive at the basis of the morbid phenomena, we must not neglect to connect these, as far as we can, with the observed alterations in particular parts. Thus the remarkable alteration of the liver, its pale and anemic condition, so opposite to either inflammation or congestion, accounts for the general absence of bile in the evacuations, at the same time that it is in harmony with the condition of the gall-bladder, which, as well as the stomach and intestines, usually contains but little bile. The gall-bladder, says M. Catel, was most usually empty. Whether the yellowness of the skin is a proper jaundice, and to be referred to disorder of the liver, has been questioned. Some are disposed to regard this yellowness, which is generally of a different shade from that of proper jaundice, darker, often mixed with a brown or mahogany tint, as dependent upon the oozing of the serum of the blood, in which, changes afterwards take place, analogous to those which occur in cases of ecchymosis. They see in this, one of the evidences of that hæmorrhagic tendency, which undoubtedly belongs to the disease. It is not improbable that both these causes may be concerned in the pro-

duction of the symptom in question. At any rate its analogy to jaundice in the parts where it commences, and in its progress, render it probable that it is connected with an imperfect elimination of bile, whilst on the contrary, certain modifications of its character may depend upon a peculiar condition of the circulating fluid, connected with a general hæmorrhagic tendency.

To the inflammation of the stomach, of course are to be referred those symptoms which are common to yellow fever and gastritis, as tenderness of the epigastrium, nausea, and the vomiting which belongs to the early and middle periods of the disease. As regards the mode of production of the black vomit, which characterizes chiefly the latter stage of fatal cases, some doubt exists. Not that there is any question that this matter is a product of the stomach itself, a position long ago maintained by Dr. Physick, and now we believe universally admitted. But it has been further maintained, that this matter was a product of the inflammation, and doubtless its secretion is favoured by this state, in numbers of cases. But that the most important element in its production is something besides inflammation, is evident, if we recollect that gastritis is a common accompaniment of other acute diseases, whilst true black vomit is perhaps never found except in yellow fever. Inflammation, then, merely as such, cannot account for it. It must be associated with some other special condition. But it is said that inflammation is not even necessary to its production, as this matter has been met with in the stomach where the mucous membrane was nearly or quite healthy. The aspect of this matter, whether vomited during life or found in the alimentary canal after death, varies considerably. Sometimes it resembles soot and water, at others it is of a brownish black, very thin and mixed with black flakes, or finally it is more consistent and presenting more or less the characters of pure blood. It would seem, indeed, that this fluid, in transuding through the mucous coat of the stomach, was in some cases altered by a true secretory process, whilst in others it escaped almost or quite pure. But this transudation is, as before mentioned, no mere consequence of inflammation, and not even necessarily connected with it, and although often favoured by it, is intimately associated with another condition, viz., the general tendency to hæmorrhage. Even this, perhaps, will not account for it fully, for it sometimes, as where it resembles a mixture of soot and water, offers more or less the characters of a peculiar secretion. Again, as before mentioned, it more or less resembles blood, and this seems to be now generally regarded as its principal constituent. We must view it, therefore, as in part at least connected with the general tendency to hæmorrhage which constitutes so prominent a feature of the disease. This feature is manifested in various ways. Thus, to say nothing of the discharge by stool of pure blood, or of a black matter analogous to that already described, hæmorrhages are occasionally noted as occurring from the mucous membrane of the nose, mouth, eyes, &c., and are, as we have already seen, most remarkably frequent in the substance of the lung, constituting pulmonary apoplexy.

*Causes.*—The origin and mode of propagation of yellow fever have been the subject of much discussion. No evidences of its existence are to be met with amongst the ancient writers. The notices in Hippocrates of violent fevers with yellowness, must clearly be referred to remittents, which now, as when he wrote, prevail in Greece, Asia Minor and the Islands of the Archipelago, where, however, yellow fever is ~~very~~ <sup>scarcely</sup> unknown. The great theatre of its ravages, indeed, is the West India islands and the neighbouring portions of the American Continent. From time to time it has been met with in some of the more northern cities on the Atlantic coast, in some parts of the southern coast of Europe, particularly that of Spain, and at a few points on the western coast of Africa. The sphere of its prevalence is, therefore, very limited, and as regards most of the places mentioned, it has been much disputed, whether the disease originated in them from local causes, or had been brought thither from other points. This brings us to the subject of contagion and infection, in reference to which we shall merely state the few conclusions which seem to be most fairly deducible from the numerous statements which have been advanced.

That the disease is properly contagious is an idea now very generally abandoned. It is agreed on all hands that an individual affected with it, if removed from the "infected district," will not communicate it to another person. These infected districts are of limited extent, and principally met with in points on the sea-coast or the shores of large rivers, where the population is numerous; rarely, if ever, in interior and elevated districts. It should also be mentioned that in the cities of the United States, the disease first shows itself on the river side and along the docks where ships are moored, and sometimes does not extend to any great distance beyond. Whilst, however, it is admitted that the danger of contracting the disease is confined to certain limited districts, that beyond these it cannot be transported by individuals affected with it, it is equally clear that vessels of a certain size may become theatres of infection, as well as places on shore. Whether this can arise from certain conditions of the vessel itself, or depends in all cases upon the retention of an infection which has been acquired in an infected port, we will not undertake to inquire. Still less would we undertake to determine, whether in certain cities of the Atlantic coast of North America, Philadelphia for instance, the origin of the different epidemics of which it has been the seat, is to be traced to vessels so infected. I should be far from maintaining such a proposition; but at the same time it is undoubted that a vessel, as just mentioned, may be the seat of infection, and convey the disease from place to place. Instances of this kind are too numerous to admit of question. Even Dr. Rush records an instance of this sort in his account of the fever of 1798 in this city. The ship *Deborah*, shortly before arrived from the West Indies, was moored at Kensington, a village to the north of the city, "where," says Dr. R., "the foul air which was emitted from her hold produced several cases of yellow fever, near the shores of that village." Whether under such circumstances, the cases of fever are limited to such persons as are exposed to the effluvia from the vessel, or whether this may become a centre of infection which will gradually spread even after the removal of the vessel, is a point about which much difference of opinion has existed, and, indeed, such is the contradictory character of the statements made by different persons, that a rigorous conclusion can scarcely be attained. One thing, however, is quite clear, namely, that if the disease ever does spread extensively from such a source, it must be under very favouring circumstances of climate, season, and temperature. So far as the northern Atlantic cities are concerned, it has always prevailed in the warm season, commencing usually in August and terminating upon the approach of cool weather. But supposing that an infected vessel cannot give rise to an extensive prevalence of the disease in any port where she may arrive, and that those only are exposed to any danger who are brought within the sphere of her contaminated atmosphere, there is still sufficient reason why quarantine regulations in this respect should not be entirely abandoned. Not that we would advocate the detention of passengers, or even of a vessel for any length of time; but we maintain that it would be unjustifiable to allow a vessel which, during the warm weather, had just arrived from a port where the yellow fever was prevalent, to be moored in the dock of a large city and there unload, when the risk could be in great measure if not entirely obviated, by opening her hatches at some convenient place in the neighbourhood, ventilating and purifying her hold, and removing such articles of her cargo as are most likely to retain any infectious principle. That such a principle is capable of transportation, even though the disease itself be not properly contagious, is not at all unreasonable; for where a vessel, for instance, has taken in her cargo at an infected port, what is to prevent such an amount of the infectious principle being retained in her hold, as, when opened in another place, will be sufficient to communicate the disease to those exposed to it. But upon whatever principle we may account for it, the fact is undoubted, and Dr. Rush mentions instances where the disease has been transported even by trunks of clothes. On the other hand, it cannot be too strongly insisted on, that the disease is not properly contagious, that there is no effluvia generated by one patient which will communicate the disease to another, in a healthy district. Such, at least, experience has hitherto proved to

be true, though at the same time, it would be hazardous to assert that under no circumstances could the disease be communicated from one person to another by a kind of infection bordering on contagion.

As regards the real sources of the infection in the districts where the disease prevails, nothing certain is known. That it is very different from the malaria of remittents, is sufficiently evident, if we reflect that the latter prevails extensively in all climates where certain conditions of heat, moisture, and soil are present, whilst the geographical distribution of yellow fever is very narrow. Not only so, but it is generally met with in positions which do not give rise to remittents, as in portions of densely populated towns where remittents do not exist. Thus for instance in Philadelphia, yellow fever has never prevailed except on the Delaware side and along the docks, where no sources of marsh malaria exist and where remittents are unknown; whilst on the other hand, the latter occur annually on the outskirts of the city on the opposite side and in the neighbourhood of the Schuylkill river, where yellow fever is and ever has been unknown, but where the ordinary conditions of marsh malaria are abundantly present. At St. Pierre (Martinique), says M. Catel, intermittents are unknown, a proof that malaria is foreign to the production of yellow fever there. The disease, then, cannot be traced to marsh malaria, and it is equally impossible to attribute it to heat which exists to as great an extent in climates where the disease is unknown, as elsewhere. In short, we can trace the disease neither to marsh malaria, to contagion, nor to any appreciable atmospheric condition, as its efficient cause, however much some of the latter, as heat and moisture, may favour its extension and severity.

*Mortality and other Circumstances.*—The mortality is very various at different times. At Fort Royal, between the years 1820 and 1827, it varied in different years from one in  $2\frac{1}{2}$  to one in 5. During the late epidemic, it was one in 6.<sup>a</sup> The disease is generally less severe amongst women and children than among adult males. Those of feeble constitution are also said to be less liable to it than those of strong plethoric constitution. In some epidemics, women and even children have been found to be entirely exempt. Between the tropics it is commonly much less likely to attack the natives and permanent residents, than foreigners or those lately arrived. Negroes, also, are less liable than whites.

Although from time to time, instances are met with of persons having the disease a second time, it is generally agreed that those who have once passed through the disease, are on that account much less liable to a future attack. Proofs of this fact, on a large scale, were furnished to the French Commission at Gibraltar.

*Treatment.*—Very different modes of practice have been instituted in this disease, not merely at different times, but in the same epidemic; still, however, the value of no particular method has been established on such grounds as to command the general assent of medical men. Some have placed their great reliance upon active and vigorous depletion; others extol calomel carried to the extent of salivation; Dr. Rush was a warm advocate of both. As regards general depletion, it can scarcely be doubted that where the patient is vigorous, the headache severe, the skin hot, and the fever in short of a sthenic or inflammatory character, this remedy proportioned to the state of the system, is decidedly proper and advantageous at the outset of the disease. On the contrary, where the fever is of a more congestive character, the pulse compressible, the heat moderate, &c., the use of the lancet may be of doubtful utility or absolutely improper. In the late epidemic at Gibraltar, the medical men of the British army bled largely at the commencement of the epidemic, but afterwards discontinued the practice, or used it only as an auxiliary to purgatives and large doses of calomel, this last becoming to be regarded as their sheet anchor. The practice of the Spanish physicians in the town was much milder. It consisted of laxatives, as castor oil, at the commencement; enemata, at first emollient, and afterwards, where the gastric symptoms were severe, somewhat purgative; acidulated drinks in the early stage, and afterwards, when the patient

<sup>a</sup> That of Gibraltar, according to Louis, was one in  $6\frac{1}{2}$ .

became more feeble, draughts containing distilled water of orange flowers and lemon peel, or where the debility became greater, an infusion of bark, or a little broth and wine. Vinegar and water lotions were used when the skin was hot, and mercury resorted to in very severe cases only. The inhabitants of Gibraltar regarded the latter practice as more successful than that of the British army surgeons, and at first sight, this opinion would seem to be justified by the results, for in the army the ratio of mortality was one in four and a half, whilst in the city it was only one in six. We are reminded, however, by M. Louis, that the patients of the army surgeons were mostly robust individuals, men in the vigour of life, whilst in the city, the male patients were less robust, and a large proportion were women and children. Now if we consider that the disease was less severe amongst the latter, and take this circumstance into the account in estimating the comparative mortality under the different plans of practice, we can no longer attribute to either any decisive superiority in the result.

In the late epidemic at St. Pierre, M. Catel placed his chief reliance upon general bleeding, pushed to the extent of producing syncope, at the outset of the attack, followed by topical depletion to the epigastrium or elsewhere as the symptoms required, associated with the use of cool drinks, mild enemata and other adjuvants of an antiphlogistic course, with sinapisms or blisters to the epigastrium, to allay the vomiting. His success appears to have been very great, the mortality being only one-eighth. On the other hand, at Dominica, it is asserted by Dr. Inray, who has practised in the colony for a number of years, that the antiphlogistic treatment had to be abandoned, and that the most active stimulants had to be resorted to in order to save life. Upon the whole, it may be stated, that however proper either of these extreme methods may be under particular circumstances, a mild antiphlogistic course, with the use of calomel in severe cases where it is really requisite, is most commonly demanded. The indiscriminate employment of calomel, carried to the extent of salivation, can scarcely be considered as justifiable. Cold affusion has been said to be very serviceable, and even to have cut short the disease, when employed at the very commencement. Cool sponging when the skin is hot, is no doubt salutary and agreeable, as in other fevers.

Emetics are often hurtful, and on the whole are condemned by most practitioners.

Of late years the experiment of giving large doses of quinine in the forming stage, has been tried in this country, and it is said, with the most happy effects. It has been given in one very large dose, from 20 to 60 grains, and with the effect, it is said, of completely breaking up the morbid condition.

Dr. Stevens's practice of administering neutral salts is described by Dr. Elliotson.

## PART III.

### LOCAL DISEASES.

---

#### BOOK I.

##### CUTANEOUS DISEASES.

I HAVE spoken of those diseases which may affect various parts of the body—inflammation and different structural diseases—and have termed them “*general diseases*.”<sup>a</sup> I have spoken, likewise, of certain diseases which appear to pervade, nearly or entirely, the whole of the body; and may be called “*universal diseases*.”<sup>b</sup> I now come to the affections of particular parts; and I said<sup>c</sup> that I should proceed from the head to the foot,—*a capite ad calcem*;—that being as good an arrangement as any; and much more serviceable than an alphabetical arrangement; for, in this way, diseases which are situated in contiguous parts, and must therefore have many symptoms in common, are considered together.<sup>d</sup> Before we begin with the head, it will be better to consider those which affect the surface; and after we have gone over the surface, we can proceed into the interior.

The diseases of the surface of the body are commonly called “*cutaneous diseases*.” They are far more numerous than would be supposed from the works of Dr. Willan, and his pupil Dr. Bateman.<sup>e</sup> Their works may be considered as the same; for the labour and honour was Willan’s; and Dr. Bateman added little to what he learnt from his master; who was profoundly read in cutaneous diseases, and had laboriously observed them. The best work on cutaneous diseases I conceive to be that of a French writer,—Rayer.<sup>f</sup> He treats of all the diseases of the skin and its appendages;—thus taking a more enlarged view than Willan; and he treats of a much more considerable number of affections of the skin itself. When I say that Rayer’s is altogether a much better book than Willan’s, I do not at all wish to depreciate the latter; for a great part of the merit of Rayer’s is ascribable to Willan. As far as Willan went, Rayer is under great obligations to him. Willan preceded Rayer; and the arrangements of the latter, in reference to the subjects treated of by the former, are grounded altogether on his publication. Rayer’s is the best book;—on account of its arrangement, the greater number of diseases of

<sup>a</sup> See Page 71.

<sup>b</sup> See Page 216.

<sup>c</sup> See Page 70.

<sup>d</sup> The advantages which Dr. Elliotson here contemplates, are best secured by Dr. Fletcher’s “*Physiological Arrangement of Diseases*,” which has been published, as a Chart, by Butler, Medical Bookseller, St. Thomas’s Street, Southwark.

<sup>e</sup> “*Description and Treatment of Cutaneous Diseases*; by Robert Willan, M. D.” “*Practical Synopsis of Cutaneous Diseases*; according to the Arrangement of Dr. Willan; by Thomas Bateman, M. D.” With the generality of readers, Dr. Bateman’s reputation is as great as Willan’s;—just as smatterers in phrenology speak of Gall and Spurzheim as equal; though the originality and glory is all Gall’s; and his pupil, Dr. Spurzheim, learnt the science from him; worked under Gall, as his assistant; and has merely added to and improved upon Gall (if he *has* added and improved; which I will not deny); and stands at a humble distance from his master.

<sup>f</sup> “*Traité Théorique et Pratique des Maladies de la Peau*, par P. Rayer; accompagnés d’un Bel Atlas de 26 Planches, Gravées et Coloriées avec le plus grand soin; représentant, en 400 figures, les Différentes Maladies de la Peau et leurs Variétés.” This work, published at Paris, has been translated into English by Dr. Willis.

which it speaks, and the fuller and more scientific account of the nature, causes, and treatment of the diseases.

*Rayer's Classification.*—Rayer divides the diseases of the surface of the body into four groups:—I. Diseases of the skin itself. II. Diseases of the *appendages* of the skin;—such as the nails, and the cutis which furnishes the nails. In this division are to be found whitlow, and morbid affections of the nails, the hair, and sebaceous follicles;—such as plica polonica, baldness, grayness, &c. III. Foreign bodies which sometimes beset the skin; as others do the intestines. These are divided into “inanimate” and “animate;”—*inanimate*, such as the sebaceous matter on the scalp of new-born infants;—*animate*, which (I need not say) include fleas, bugs, and lice; together with certain other animals of which we shall speak. IV. Those affections which commence in other parts of the body; and afterwards implicate and disfigure the skin; such as the disease called “elephantiasis;” in which the skin becomes implicated only secondarily. The whole describes, in a very comprehensive way, the diseases of the surface of the body.

Then, again, truly cutaneous diseases are arranged by Rayer into six classes:—1. All those diseases of the skin which are *inflammatory*. 2. Those which are mere *congestions*; and cutaneous and subcutaneous *hæmorrhages*. 3. Those which are *nervous* affections of the skin;—such as morbid or deficient sensibility of it. 4. Changes of *colour* in the skin;—not at all dependent upon congestion. 5. Morbid *secretions* of the skin. 6. Diseases of the *structure* of the skin. This is a very useful view of diseases of the skin itself.

*Willan's Arrangement.*—They are arranged by Willan without any reference to their real nature. He arranges cutaneous diseases, as follows:—1. Mere pimples, without any contents;—“*papulæ*.” 2. Scaly;—“*squamæ*.” 3. Diffused patches of redness;—“*exanthemata*.” 4. Collections of water;—“*bullæ*.” 5. Secretion of pus;—“*pustulæ*.” 6. Little vesicles;—“*vesiculæ*.” 7. Tubercular appearances on the skin;—“*tubercula*.” 8. those in which there are stains;—“*maculæ*.”<sup>a</sup> Several sets of diseases thus arranged by Willan, come together in the arrangement of Rayer, under the one head of “inflammatory diseases.”

Willan's work (and Bateman's) is rather one of Natural History than Pathology. His delight and excellence are in the description of appearances. Rayer's work is excellent for deeper matters. This is the natural progress of knowledge. First, perfection is attained in distinguishing the *outward appearances* of objects and phenomena; and, this accomplished, their *nature* and *causes* come next to be investigated. Willan accomplished much, though greatly indebted to foreign predecessors; but his labours were only a stepping-stone to what then became important.

*Frequently Dependent on a Diseased State of the System.*—It is very important to remember, that although these are called “diseases of the *surface* of the body,” many of them are affections of a much deeper nature;—that the affection is frequently connected with, or dependent upon, a general diseased state of the system. Frequently the mucous membranes are affected as much as the skin;—for example, the conjunctiva of the eye, the Schneiderian membrane of the nose, and the mucous membranes of the mouth, throat, and of the whole of the air-passages and alimentary canal. All these parts are liable to be affected, in some diseases of the skin. In measles, which is called “a disease of the *skin*,” we frequently have inflammation of the various mucous membranes which I have just named. So in the disease which is called “*purpura*,” and which is considered a disease of the skin (because there are purple spots on that organ), we have often the same appearances within, as upon the surface. I formerly mentioned,<sup>b</sup> that this was as much an *inflammatory* disease as one of *congestion*; and it may be *entirely* inflammatory. The intestines, the lungs, the liver, and even parts within the head, are sometimes beset with black patches: for, in this disease, blood has sometimes been effused in such quantity, that apoplexy has occurred. Although these diseases particularly

<sup>a</sup> A Chart of the various diseases of the skin, arranged according to this system, has been published by Butler, Medical Bookseller, St. Thomas's Street, Southwark.

<sup>b</sup> See Page 136.

affect the *skin*, yet in many of them, before the affection of the skin appears, there is some *internal* derangement; which occasionally ceases when the external affection appears, but which sometimes continues throughout. In many there is an internal derangement, at a certain time, during the affection of the skin. In many of these cutaneous affections, the whole system appears more or less in an inflammatory state; and in others the whole system is in a state of extreme debility,—complete exhaustion. Although, therefore, these are called “diseases of the *skin*,”—from their producing very prominent symptoms there; yet it is to be remembered, that many of them are of a more deep and extensive nature. Many, of course, are *really* local; such as a change in the *colour* of the skin,—called “*ptyriasis versicolor*,” where a person has a yellow appearance of the skin (very common on the necks of young women); and diseases of the *appendages* of the skin; such as diseases of the nails, and various affections of the hair and sebaceous glands. These are pure diseases of the integuments of the body; but many affections, called “*cutaneous diseases*,” are only cutaneous in one point of view.

*Dr. Elliotson's Arrangement.*—We see, therefore, that the diseases of the integuments of the body may be considered, in the first instance, according as they are diseases of the skin *itself*, or of the *appendages* of the skin; as there are foreign bodies upon the skin;—which cases are still allowed to be called “diseases of the skin;” or as the disease begins in other parts, and implicates the skin. We have, then, to consider whether cutaneous diseases, like others, are inflammatory or not; and we therefore group together all those that are inflammatory. Then all those are naturally grouped together that depend upon congestion; such as ecchymoses, cutaneous tumours, and subcutaneous bloody tumours,—sometimes called “*nævi materni*.” Thirdly, those which are seated in the nerves of the part; fourthly, changes of mere colour; fifthly, morbid secretions; and, sixthly, malformations, and structural changes of the skin. In this way we shall bring before us all the diseases of the skin itself.

The *inflammatory* diseases of the skin are arranged by Rayer, first, as they occur in *patches* of inflammation,—“*exanthemata*,” then, as they produce collections of *water*,—“*bullæ*,” then, as there are *minute* collections of water,—“*vesiculæ*,” then, as there is suppuration,—“*pustulæ*,” or as there is *more extensive* suppuration,—“*furunculi*,” then, as there are mere *specks* of inflammation,—“*papulæ*,” then, as there are *tubercular* appearances,—“*tubercula*,” then, as there are *scales* produced,—“*squamæ*,” then, as there is inflammation in *lines*,—“*linear* inflammation,” then, as there exists a disposition to gangrene,—“*gangrænosi*” (as plague, malignant pustule, and glanders); and then he makes a class called “*multiform*,” in which diseases have no fixed appearance (such as syphilis). It appears to me, that the most simple way of considering these inflammatory diseases, is to consider them, first, when the inflammation is in the most *minute extent*;—simple inflammation not larger than the point of a pin;—“*papulæ*.” Then we shall come to a more extensive inflammation,—“*exanthemata*,” then, to one which produces a little collection of *water*,—“*vesiculæ*,” then to a *large* collection of water,—“*bullæ*,” then, where *pus* is secreted,—“*pustulæ*,” then, where *pus* is secreted in *larger quantity*,—boils, or “*furunculi*,” then to where the inflammation proceeds to *gangrene*; then where there is *organic* disease;—first of the *slightest* kind (only of the *cutis*) as in the “*scaly diseases*,”—then of a kind seated more deeply, as in the “*tubercula*,” and thus we shall go on in a more natural way, than that which Rayer has adopted.

## CHAPTER I.

## PAPULÆ.

*Definition.*—WE now enter upon the consideration of inflammatory diseases of the skin itself; and, in the first place, we shall speak of those which produce no secretion whatever;—no pus, no water; but which consist simply in inflammation, and that of the most limited extent;—producing a little *speck* of inflammation. Of course there may be a *number* of these little spots. When inflammation of the skin appears in minute spots, these are called “*papulæ*,” the English of which is, strictly speaking, “*pimples*.”<sup>a</sup> The word “*pimple*” is commonly used to signify any little elevation or inflammation of the skin;—whether there are no contents, or whether there is water or pus; but, in strictly correct language, by a “*pimple*” is meant a minute inflammation of the skin, causing a very small acuminate elevation of the cuticle, without any contents whatever. Dr. Willan’s definition of a papula, or true pimple, is—“a very small and acuminate elevation of the cuticle” (I should suppose of the cutis and the cuticle together), “with an inflamed base; not containing fluid; not tending to suppuration. The duration of *papulæ* is uncertain; but they terminate, for the most part, in scurf.”<sup>b</sup> If such a slight inflammation be attended by watery contents, it is called a “*vesicle*,” but if the contents be pus, we call it a “*pustule*,”—so that with respect to the most minute inflammation of the skin, we have a papula, a vesicle, or a pustule;—in other words, mere *inflammation*, inflammation with *water*, or inflammation with *pus*.

*Progress and Termination of Papulæ.*—Where these *papulæ* (which are, more or less, of a red colour) occur, there is experienced an uneasiness, which may be called pain; but it is pain of an itching character;—a “*painful itching*,” we might say. Inflammation of this description may end in resolution, without any formation of scurf; or it may terminate in a more extensive separation of the cuticle, which is called “*desquamation*,”—a separation of the skin in scales. For the most part, however, the cuticle is separated in such minute portions, that only a fine dust (*scurf*) comes off; which will take place, not only with evident inflammation, but sometimes with so exceedingly slight a degree of inflammation, that we can hardly call it more than “a little irritation.” A new cuticle is found underneath the exfoliation. There is no rawness produced; but, under the minute portion of cuticle which comes off, we see a fresh cuticle. There is no moisture at all;—the parts being still perfectly dry. If this inflammation be increased by the person rubbing or scratching the part, or by heat improperly applied, it may proceed to the formation of water;—so that we convert the papula into a vesicle. Again: if we add still more irritation, we may cause it to produce pus; and so convert it into a pustule. If the individual scratch himself still more, and great irritation be excited, instead of mere pustules we may have boils;—pretty large collections of pus; but all this is not the tendency of the disease itself. These *papulæ*, which consist of mere spots of inflammation, are not contagious.

*Seat of Papulæ.*—These *papulæ* are considered, by Dr. Willan, as inflammations of the papillæ of the skin; which he considers to be enlarged, elevated, and indurated; but I should think, if it be the papillæ which are inflamed, we should be justified in saying, as I have said, that there is something more than elevation of the cuticle. If the papillæ be inflamed, of course we must consider the disease as situated in the cutis;—the cuticle being elevated above the skin itself. The

<sup>a</sup> The word “*papula*” is derived from “*pappa*,” a *nipple*; and the diminutive “*ula*” (from *ula*); and signifies, therefore, “a little pimple.”

<sup>b</sup> “Description and Treatment of Cutaneous Diseases;” Definition 5.

inflamed base cannot be in the *cuticle*;—that is out of the question; and therefore it must be situated in the *cutis*.

*Varieties of Papulæ.*—Dr. Willan makes *three* kinds of papulæ. These are the “strophulus,” (or “red-gum”) of children; the “lichen” of adults; and the disease called “prurigo.” His first plate contains a good representation of them. But I think that there are only *two*; for I believe that strophulus and lichen are purely the same disease; and I think it would be better if the name “lichen” were given to both; or if both names were dropped, and one term substituted for them. The disease called “prurigo,” is characterized by great itching; and is often mistaken for itch. Neither lichen nor prurigo has any particular name in English.

## SECTION I.—STROPHULUS.

This disease is peculiar to infants; and is called, by the common people, “red-gum” or “red-gown.” It is supposed that “gum” is a corruption of “gown;” and, in some old dictionaries, it is still written “redde-gowne.” It is also occasionally called, by the common people, the “tooth-eruption.” It is a very unimportant disease. The least irritation will cause it;—whether in the gums, abdomen, or other parts of the system; and, with a very little attention, it goes away. In fact, it need never create any alarm. It is divided, by the common people, into “red” and “white.” Several parts of the body are affected in succession;—it does not come out at once. It chiefly affects the face and extremities; and is sometimes intermittent;—not *periodical*; but coming and going.

*Varieties.*—It is divided, by authors, into a number of tiresome varieties; which only serve to burden the memory, and are soon forgotten in practice. The great point which I would insist upon, at present, is to recollect the characters of diseases *in general*; and as to the particular *varieties*, we can learn them afterwards, as different cases present themselves to our notice; and then we need not trouble ourselves so much about the *names* of these varieties, as about remembering the fact that there *are* some varieties in the appearances of the affections, and some varieties in the condition of the *system*, and of the *part affected* in these diseases;—a fact that is not sufficiently dwelt upon by subdividers. It is impossible to recollect all the minute divisions of these different diseases, without seeing patients; and then it is impossible to learn them all at once. It is a work of time; and there can be no doubt it would be quite as well, if many of them were not so subdivided by authors. This particular affection is divided into:—1. *Strophulus intertinctus*. 2. *Strophulus albidus*. 3. *Strophulus confertus*. 4. *Strophulus volaticus*. 5. *Strophulus candidus*.<sup>a</sup>

If the papulæ be of a vivid red colour, but are intermixed with red dots or specks, called “stigmata,”<sup>b</sup> it is then called “*strophulus intertinctus*.” If the papulæ consist of whitish specks, it is called “*strophulus albidus*,”—that is to say, “white-gum;” and this is often intermixed with the other. If the papulæ be all united together, it is called “*strophulus confertus*,” and, by the common people, “rank red-gum,” or “tooth-rash.” It is hardly worth while to give particular names to these little variations of the disease. We sometimes observe different varieties in different parts of the same child. If the papulæ of strophulus be of large size, and have no inflammation at their base, they are called “*absolutely white*,”—“*strophulus candidus*.” This, however, is a contradiction; for a papula, according to Dr. Willan’s definition,<sup>c</sup> is “an acuminated elevation of the cuticle, *with an inflamed base*.”<sup>d</sup> This variety usually succeeds acute diseases of children a year

<sup>a</sup> These affections are represented, extremely well, in Dr. Willan’s “Description and Treatment of Cutaneous Diseases,” Plates 2, 3, and 4.

Willan, in his “Description and Treatment of Cutaneous Diseases,” (Definition 4,) defines a “stigma” (from *στίγμα*, *to inflict blows*) to be “a small, red speck, occasioning no elevation of the cuticle.”

<sup>c</sup> See page 366.

<sup>d</sup> See his “Description and Treatment of Cutaneous Diseases;” Definition 5.

old. If, after continuing some time, they produce a scurf, and then disappear, and another crop comes on, it is then called "*strophulus volaticus*;"—coming and going;—continuing but for a short time. The patches are regular, and turn brown in a few days; and the whole series ends in a few weeks. I am sure it must be difficult to remember the differences, which occasion the disease sometimes to be called "candidus," and sometimes "albidus;" the important point will be, however, not to recollect the names of these little particulars, but to remember the general character of the disease. It is sometimes pretty severe; and a great many papulæ are crowded together; and then the variety is called "*strophulus confertus*;" the papulæ are extensive, crowded, smaller, and less vivid. This form will occur in children from seven to eight months old. The patches may be hard; and they usually exfoliate in a fortnight. In this severe form, it sometimes begins in the legs, and spreads upwards to the loins and navel, with a general redness;—the cuticle cracking into large pieces; and this will occur, every now and then, for two or three months. Some children will labour under it, till they have cut all their first teeth.

*Causes.*—With regard to the *causes* of it, I believe that any little irritation of the alimentary canal will produce it. The irritation of teething, and very frequently exposure to cold,—especially if aided by wet,—will induce this, and various other inflammatory diseases of the skin.

*Treatment.*—Whether the disease appear in this aggravated form or not, one of the best things is to give mild purgatives, with some alkaline matter; as, for example, a little Liquor Potassæ, or carbonate of soda, or magnesia, two or three times a day. There is, generally speaking, acidity; which may be corrected by something of this description. Moderate aperients can be given at the same time; and the warm-bath is found particularly useful. If the disease should prove obstinate, I would certainly give Hydrargyrum cum Cretâ;—mercury in a very innocent form; but, for the most part, it is not required. There is no *essential* difference, however, in the treatment of the different varieties of this affection. Great attention should be paid to the diet; for, very frequently, the disease arises from some little error in that respect;—something improper having been accidentally (or designedly) given. If the disease suddenly disappear, we may find the child evidently in want of stimuli; and, when that is the case, a few drops of Liquor Ammoniac, two or three times a day, will be of use; particularly if it be conjoined with the warm-bath, and good nutritious food. The warm-bath is one of the most important measures that can be had recourse to, in diseases of the skin, when we want to bring out an eruption, or to encourage it. I am told that the warm-air-bath does as well; but I have no experience of it. To avoid cutaneous irritations, nurses should always *wash* infants' napkins, and not merely *dry* them.

In this disease, if we should find a pretty active inflammation of the skin, we would of course give stronger purgatives; and there might be no harm in applying leeches. If, on the other hand, we found debility, it would be well to give tonics,—iron or quina; and to order nutritious diet. Cutaneous diseases occur in all states of the body. Sometimes there is such debility, that we cannot cure the affection without the temporary use of meat, wine, porter, iron, &c.; while, in other cases, there is an inflammatory state of the body;—making it evident that bleeding must be had recourse to, and low diet. So in this disease of children, sometimes there is debility of the whole body;—the disease continuing because the whole system is out of order; and then better nourishment and tonics will be required. In other cases, local bleeding and stronger purgatives will be necessary; but, in general, all that is wanted is a warm-bath, and alkaline and aperient substances.

*Avoid Exposure to Cold.*—In this disease, be particularly careful that the child is not exposed to cold. It is dangerous to put a sudden stop to the eruption, by allowing the child to catch cold. It is possible that the eruption may cease, and that the child may fall into a state of depression; in which case the warm-bath will be required. But internal inflammation may be the result; and in that case, also,

the warm-bath may be useful; but antiphlogistic measures may be required in addition; for when eruptions suddenly cease, there is often an internal inflammation suddenly set up. It is right to know that these accidents may happen; but, for the most part, the disease is a mild insignificant affection;—more a matter of curiosity, indeed, than any thing else.

## SECTION II.—LICHEN.

This affection occurs in adults, and is similar to strophulus. Indeed there is scarcely any difference in the appearance of these diseases; and I have always been accustomed to consider them as the same;—affecting children, and called “strophulus;”—affecting adults, and called “lichen.”<sup>a</sup> When I read Rayer’s work for the first time, I was glad to find that he entertained the same opinion as myself. I always spoke of them as the same; but I thought I might be wrong; for I do not pretend to be so skilled in these matters, as those who have devoted themselves entirely to them. But Rayer says he would unite them, were it not for the fear of making more confusion, by introducing a new division in the history of papular diseases, which Dr. Willan has described with minute accuracy.<sup>b</sup> I think it had better be done; as it would simplify the matter at once, and burthen the memory with one disease and set of names the less.

*Seat and Varieties of Lichen.*—This disease, in adults, usually occurs in the extremities; and particularly on the outer and posterior parts of the extremities. The size of the papulæ is that of the head of a very small pin; and they generally terminate in scurf. The disease is sometimes acute; sometimes recurrent; sometimes chronic; sometimes general; sometimes partial; and sometimes connected with internal disease. It is divided, by authors, into—1. “*Lichen simplex*.” 2. “*Lichen pilaris*,” that which occurs particularly about the roots of hairs. 3. “*Lichen circumscriptus*,” a form in which the papulæ are clustered together. 4. “*Lichen agrius*,” a very severe form indeed. 5. “*Lichen lividus*.” 6. “*Lichen tropicus*.” 7. “*Lichen urticatus*.” In the simple form, we must expect the papulæ to be larger than when they occur in children. If they be very severe, they cluster together; the skin becomes inflamed; and they form deeply red patches.<sup>c</sup>

*Duration and Progress of Lichen.*—The simple form of this complaint lasts, generally, from ten to twenty days. Sometimes, it is preceded by nausea, vomiting, and pain of the head; and sometimes these symptoms will disappear as soon as it comes; while, at others, they will continue with it. It sometimes takes place at the end of certain cutaneous diseases; particularly after fever and catarrh, and (it is said) even after peritonæal inflammation. Some persons have it annually;—some at the beginning of summer, others in autumn; while some are so unfortunate as to have it in both. I know a young lady who had it every spring and every autumn. It was observed by the Romans, who called it “*sudamina*,” and the Greeks, who noticed it, called it *ιδρωα*. In this country, in hot weather, we often have a great tingling of the skin. It is sometimes rather a sharp disease; but there is nothing dangerous in it, though the general excitement is great. It is said, that when it occurs about the hairs (“*lichen pilaris*,”) it is often chronic. When it occurs in the severe form, called “*lichen agrius*,” there is a great degree of itching, and a great degree of heat; and the inflammation is sometimes so violent, that we have vesicles and excoriations. This severe form of the disease, is sometimes preceded and accompanied by nausea, pain at the stomach, and pain of the head; and may last several weeks. It is much more frequent in women. It corresponds with “*strophulus confertus*.” This variety is sometimes connected, but only

<sup>a</sup> “Spring-eruption,” “scorbutic pimples,” &c. (Willan.)

<sup>b</sup> See his “Description and Treatment of Cutaneous Diseases,” Order 1.

<sup>c</sup> These are well represented by Willan, Plates 5 and 6; and also in Rayer’s Work, Plate 6 (First Division).

locally and temporarily, with a pustular disease, called "impetigo;" with another, in which serum is secreted,—"*eczema*;" and another, in which scales are formed,—"*psoriasis*;" and sometimes it will degenerate into them. Sometimes, though rarely, the papulæ are livid; and the variety is called "*lichen lividus*." More frequently it is united with petechiæ; or dark spots of congestion.

*Prickly Heat*.—There is one kind of this affection, called "*lichen tropicus*," which is attended by a great degree of tingling. This is mentioned by all writers on the diseases of hot climates; and it is described by them as a most distressing affection. When a person is subject to this variety of the affection, the moment he goes to bed or takes exercise, he has a most violent pricking of the skin, called "prickly heat." It is called "*lichen tropicus*;"—from the disease occurring in tropical climates. It is not easily repelled; and its sudden cessation is generally the effect, not the cause, of an internal affection. The "prickly heat" is thought to be a sign of good health. Sometimes the papulæ, in this disease, are attended with little bumps, like the bites of gnats or bugs; and then it is called "*lichen urticatus*." It affects the neck and face,—particularly in spring and summer; and is attended by a stinging pain. But though there are bumps or wheals, still there are papulæ. It chiefly affects the neck, face, and hands. It corresponds with "*strophulus candidus*."

*Treatment*.—In all these forms of the disease, the treatment is to be the same as in the strophulus of children. If there be great excitement of the system, and headache, we should bleed. If a patient have a strong pulse, even *without* excitement, by far the shortest way is to take a little blood from him, put him on low diet, purge him well, and order him the warm bath. Do not allow the *hot*-bath; for, if we apply much heat to the skin, we shall in a great number of cases make matters worse. Just as in the case of strophulus of children, purgatives (especially combined with alkaline matters) given two or three times a-day, and low diet, will usually remove lichen; but if the disease be severe, the shortest way is to bleed in the arm in addition. Even if the severity of the disease do not *indicate* this measure, yet if the constitution of the patient and his pulse *justify* it, I should still have recourse to it.

*Local Applications*.—For the relief of the parts themselves, which are tingling and itching, the chlorides of lime and soda answer better than any thing else.—Many persons use vinegar for this purpose; and it answers pretty well; but I think that, in all cases where there is itching of the skin, if that organ be sound, and the chlorides be properly diluted, they are by far the most serviceable. I have known some persons relieved by the application of prussic acid, of the strength of a drachm<sup>a</sup> to eight ounces of water;—sometimes stronger. I had an old man at St. Thomas's Hospital, with great inflammation of the legs, connected with varicose veins;—which is certainly not exactly this disease; but nothing relieved him except prussic acid;—one ounce<sup>a</sup> to a pint of water. Sometimes, however, this will produce heat and tingling; and it is best not to use at first more than a drachm<sup>a</sup> or two drachms<sup>a</sup> to a pint; but, if this produce no effect, increase it. Occasionally there is great heat and dryness induced by applying it in greater strength.

Bleeding at the arm, low diet, and purging, are the best general means, and, as local remedies, either vinegar, prussic acid, the chlorides, or plain water, warm or cold.

### SECTION III.—PRURIGO.

*Symptoms and Progress*.—In prurigo,<sup>b</sup> the papulæ are very little discoloured;—being nearly the same colour as the skin; but they are larger than in lichen. They are particularly characterized by itching; which is a far more striking symptom than the eruption itself. That is not the case in the two affections already

<sup>a</sup> Of the official preparation,—"*Acidum Hydrocyanicum Dilutum*."

<sup>b</sup> From "*prurio*," to *itch*.

described; except in that form called "*lichen tropicus*." In the latter there is a very severe eruption; whereas, in prurigo, the eruption differs but little from the adjoining skin. The papulæ also vary from those of lichen, in not being so pointed. So severe is the itching, that people scratch themselves, till they rub off the surface of the papulæ. A little blood exudes;—a very minute portion; and then it forms a little black crust; so that the papulæ will have an artificial black top; and, from scratching them, water will ooze as well as blood. This, however, is incidental; and has nothing to do with the complaint. If the patient will continue to scratch, he may cause these papulæ to be converted into vesicles; if he scratch still more, suppuration will take place, and he will have pustules; and the skin may even be brought into such a state, that it will crack, and become indurated and hypertrophied. This is a chronic disease. Lichen and strophulus are sometimes chronic, and sometimes acute; but prurigo usually lasts a considerable time, unless properly treated at an early period.

*Prurigo Mitis*.—If the disease occur in the mildest form, it is called "*prurigo mitis*." This chiefly affects the young. The disease altogether, in every variety, affects both the young and the old; but that called "*prurigo mitis*" principally affects the young; and occurs particularly about the spring or beginning of summer. It is said, by some, to degenerate into the itch; but others deny this. Sometimes the eruption is scarcely visible at all. There is intense itching; but it is rather difficult to find out any eruption. It will remit; and sometimes it will *intermit*,—come and go entirely.

*Prurigo Formicans*.—If it be very severe, there is an epithet added to the word "*prurigo*," to signify great intensity; and, from the itching resembling so much the bite of an ant ("formica"), it is called "*prurigo formicans*;" which is a very severe,—I may say, a *dreadful* disease. It affects adults at all periods, but not children; and it occurs in every part of the body, except the palms of the hands and soles of the feet. Occasionally it is preceded by feverishness, pain of the head, and sickness.

*Prurigo Senilis*.—There is a third form, which is confined to old age; and which is called "*prurigo senilis*;" and this is likewise a very severe form of the disease. I should sometimes be at a loss to distinguish between "*prurigo formicans*" and "*prurigo senilis*;" for the former only occurs in old people. I think it would be better to say, that prurigo is a disease which sometimes is mild, but now and then severe. If it attack old people, it generally continues very obstinate, for a great length of time.\* There are no scales, or scabs, or water; nor is there any pus.

*Local Varieties of Prurigo*.—This disease is sometimes local; attacking a particular part of the body only; and not being diffused. It affects, particularly, the scrotum of the male, and the pudendum of the female. The scrotum, from constant irritation,—from the patient everlastingly scratching himself, becomes scaly, and very much indurated. It will attack the prepuce; and then it is called "*prurigo præputii*." Sometimes it has occurred within the urethra;—"prurigo urethralis." It will sometimes affect the extremity of the rectum;—"prurigo podicis." The worst seat of it, however, is in the pudendum of the female;—"prurigo pudendi muliebris;" and there it is sometimes very violent,—very distressing; so that a woman cannot go into society at all. She cannot appear before men; nor, indeed, can she appear before strange *females*; in consequence of her being under the necessity of scratching herself. I have known women driven almost mad, with the vexation of finding that they were not able to pass five minutes without scratching themselves violently. I saw one woman, who was obliged to get up several times in the night. She was unable to go to sleep; for, at last, the heat became so great, that she was compelled to get out of bed, and wash herself with cold water; and so she had passed every night, for months, when I saw her. The vagina and

\* These forms of Prurigo are well shown in Willan's Work on the "Description and Treatment of Cutaneous Diseases;" Plate 7.

the inner surface of the labia, in very severe cases, become thickened; and small indurated masses are formed here and there. The latter are not properly tubercles; but have a tuberculated appearance. When this occurs in females, it excites a desire of copulation; which, as they have told me, relieves it for a time; but, in a little while afterwards, they are worse than ever. It is impossible for them to get relief, in this way, every moment; and I advised the woman to whose case I had just referred, and who told me that she lived separately from her husband, to use nothing but cold water. It is really, though not dangerous to life, a distressing disease; and women will cry, and absolutely wish for death, when they are labouring under it. I cannot conceive any thing more lamentable; and, if it occur to a modest woman, it is the most horrid sort of case that can come before us. It rarely occurs in females before the middle period of life. Dr. Willan<sup>a</sup> says, that aphthæ may appear on the nymphæ, and internal part of the labia; and may be communicated to the glans penis, and internal part of the male prepuce; that they are easily cured; and that these aphthæ, as well as "prurigo pudendi muliebris," often occur after the fourth month of pregnancy.

*Causes.*—[Dr. Willan<sup>b</sup> attributes the milder form of prurigo to "sordes collected on the skin, producing some degree of irritation, and also preventing the free discharge of the cutaneous exhalations; the bad consequences of which must necessarily be felt at that season of the year, when the perspiration is most copious." Hence he considers, that those who have originally a delicate or irritable skin, will in such circumstances be the greatest sufferers. The more severe form of prurigo ("prurigo formicans") is generally, according to Dr. Willan,<sup>c</sup> attended with an unhealthy condition of the system, consequent on grief, watching, fatigue, and poor diet. As, however, the concurrence of these circumstances will not, in all cases, produce this disease; Dr. Willan conceives<sup>c</sup> that it must, in part, be referred to the original texture of the skin, or the state of the cutaneous glands. In support of this opinion, he states<sup>c</sup> that "the greater number of cases had a more than usual coarseness or roughness of the skin; which seemed often to have been communicated hereditarily; and that when the itching and papulæ disappear at the termination of the disease, the cuticle is left dry, scaly, and thickened." Want of proper cleanliness is also a frequent cause of this disease among the lower classes. "Certain modes of diet" (according to Dr. Willan<sup>c</sup>) "have likewise a considerable effect in aggravating or exciting the prurigo formicans. Many persons are affected with it, who in the summer season live much upon fish and other stimulant animal food; at the same time drinking freely of wine or spirituous liquors. Some of the white Spanish wines excite, in particular habits, an eruption of itching papulæ; which is excessively troublesome for many hours afterwards; but does not become permanent, if the beverage be discontinued."]

*Effects and Duration.*—This disease is not dangerous to life; but it is sometimes really a most dreadful disease;—"dreadful," I mean, so far as suffering is concerned; and, for what I know, it may injure the general health. I have known imbecility of mind sometimes caused by the intense suffering it occasions. The intense suffering has continued, month after month; and, indeed, year after year; and has produced such depression of spirits, and such exhaustion of mind, that persons have become imbecile,—really worn down; and a sort of fatuity has arisen from mere exhaustion. I once had a man come to me, in this state, at St. Thomas's, when I attended the out-patients. He pulled off his coat, uncovered his bosom, and showed me every part in an instant;—he was so quick in all his movements. He then pulled a comb from his pocket; and assured me that was the second comb he had bought;—having worn out the first in scratching himself.

<sup>a</sup> See his "Description and Treatment of Cutaneous Diseases," Order 1; Genus 3; Species 6.

<sup>b</sup> See his "Description and Treatment of Cutaneous Diseases," Order 1; Genus 3; Species 1.

<sup>c</sup> See his "Description and Treatment of Cutaneous Diseases," Order 1; Genus 3; Species 2.

I have no doubt this was true. The itching was most intense; and he had been in this state two or three years. Some years ago, I had a man who came to the hospital; and whose sufferings had been nearly as intense. The idea had not occurred to him of buying a comb; but he used his nails well in scratching himself. His mind was as much gone as that of the other patient. He was really falling into childishness.

*Prurigo Mistaken for Itch.*—The mild form of prurigo may be mistaken for itch. I will not point out the diagnosis now; but advert to it when I speak of itch. I may mention, however, that it will occur in every part of the body. It will occur in the face, as well as other parts; but the itch, I believe, will not. Prurigo, too, is not a contagious disease.

*Treatment.*—With regard to the treatment, supposing it to be the mild form of the disease, it is right to make the patient avoid stimuli of every sort;—pepper, mustard, wine, beer, &c. Many persons have a tingling, immediately on taking certain articles. If I take a grain or two of pepper, or taste vinegar, I have an itching of the scalp; and, wherever I am, I must begin to scratch my head. If I take opium, I have a violent tingling of the nose, for many hours afterward. Now all these matters, especially mustard and pepper, are likely to increase the affection. If a patient will bear it, it may be right sometimes to take blood. At any rate, it is proper to purge him moderately; and I should advise alkalies;—as there is often acidity in the stomach. But there is a remedy from which I have found greater relief, than from any other; not in the *mild* form only, but also in the *severe*; and one of the men I have just mentioned, was cured by it;—at least, he was so far relieved, that I could keep him no longer in the hospital. That remedy is colchicum. I am sure that purging with colchicum will produce more benefit than any thing else. In the mild form of the disease, undoubtedly, this is the best remedy. Patients should avoid going near the fire, or taking much exercise, so as to irritate the skin; but I am quite satisfied that colchicum is the best remedy we can employ internally.

*Local Applications.*—As to the itching itself, that is very much mitigated by diluted acids, such as vinegar; and also by the chloride of lime, or of soda. These produce a very great mitigation of the itching. We also find relief, sometimes, from a fomentation of prussic acid. The woman who was so bad from “*prurigo pudendi muliebris*,” found great relief, for a time, from applying prussic acid. She used it, at length, to such an amount, and of such a degree of strength, that it produced giddiness and fainting;—so that she could not stand it; and yet it did not cure her complaint. It appeared, at last, that the best thing was a cold application; and, therefore, she had a pail of water brought into her room at night, and used it very frequently. I believe this local prurigo will arise, occasionally, from some local cause of irritation. Worms in the rectum, will produce “*prurigo podicis*,” and a stone in the bladder, is sometimes attended with a violent itching of the prepuce. In women, it sometimes attends structural disease of the womb. It is right to endeavour to ascertain whether there is a local cause; and, if there be, we must endeavour to remove it; but if we cannot find a local cause, then (I believe) the application of the chlorides, or prussic acid, or cold water, is the best thing. Some tell me that they have seen great relief from what is called “the yellow wash;”—bichloride of mercury and lime water. It is much about the same thing as using the chloride of lime. The French use sulphureous baths, and emollient baths containing gelatine; but I have no experience of them.

## CHAPTER II.

## EXANTHEMATATA.

WE now proceed to another class of diseases;—a class in which the redness is not confined to spots, but forms patches. Such diseases as these are called “exanthemata,”<sup>a</sup> or (in English) “rashes;”—a “rash” being an extensive redness of the skin. In these diseases there are not pimples or spots, but patches;—the same thing precisely, only of greater extent. They are defined by Dr. Willan<sup>b</sup> to be “red patches, variously figured, in general confluent, and diffused irregularly over the body; leaving interstices of a natural colour. Portions of the cuticle are often elevated in a rash; but the elevations are not acuminate. The eruption is usually accompanied by a general disorder of the constitution, and terminates, in a few days, by cuticular exfoliations.” The former class of diseases (“papulæ”) it will be remembered,<sup>c</sup> either terminated without any thing following, or induced a scurf. These being a more extended redness,—being patches instead of pimples, are followed, not by scurf, but by an exfoliation of the cuticle. Large portions of cuticle separate; and therefore, instead of being branny or scurfy, it is in plates. These exanthemata often render the surface uneven, by elevating the portions affected. The brightness is variable; and sometimes, Willan<sup>d</sup> says, extravasation occurs.

The chief diseases of this description are, in the first place, “erythema” and “roseola;” which I will unite together (or endeavour to do so), as I did lichen and strophulus. The next is “measles;” the next “scarlatina;” and then comes “urticaria.” Some of these are contagious, and others not. None of the first class were contagious; but two of these are;—namely, measles and scarlet fever. These two usually occur but once during life. The two first of these affections are very slight; just like lichen and strophulus; and are not contagious.

## SECTION I.—ROSEOLA.

*Characters of the Eruption.*—Roseola<sup>e</sup> is described as consisting of rose-coloured patches, without wheals, little bumps, papulæ, or minute elevations of the skin; and these patches are circular or oval.<sup>f</sup> It occurs at all ages, but especially affects children; when it is called “roseola infantilis.” There is sometimes an itching attending it; and sometimes only a tingling. The patches are of all sizes, and are sometimes diffused very generally over the body; but if not, still they are pretty numerous. If the patches be round, it is called “roseola annulata.” Sometimes there is a little feverishness, or a little irritation of the bowels; and those symptoms generally occur from two to seven days before the eruption appears. It is usually a superficial complaint; very innocent to the body; very short in its duration; and, after it, there is scarcely any exfoliation. The character of this eruption is said (by Rayer) to be that, after pressure, the redness returns at all points. In scarlet-fever, if we press the rash, the redness, on removing the finger, returns from the circumference of the part; but, in roseola, every part recovers its redness at the same time. I never made the observation myself; and therefore cannot answer for its accuracy. Now and then it might be mistaken for scarlet-fever; but, he says,

<sup>a</sup> From *εξανθεω*, to *effloresce*.

<sup>b</sup> See his “Description and Treatment of Cutaneous Diseases;” Definition 6.

<sup>c</sup> See Page 366.

<sup>d</sup> See his “Description and Treatment of Cutaneous Diseases;” Order 3. (Pages 213 and 214.)

<sup>e</sup> From “*rosa*,” a *rose*.

<sup>f</sup> It is well shown in Willan, Order 3; Genus 4; Plates 25, 26, and 27.

that we may distinguish between the two affections, by noticing what I have just stated.

*Duration and Varieties of Roseola.*—It is a trifling eruption, and seldom lasts more than four or five days; so that it never becomes chronic, unless there be many attacks of it;—unless it be remittent. If it come and go, a patient may be troubled with it for a length of time; but the disease never remains incessantly, for any long period. In the spring and summer, it will no doubt frequently arise from the heat of the weather, but frequently it happens without any evident cause whatever. If it occur in the summer, it is called "*roseola æstiva*;" but if it occur in the autumn, it is designated "*roseola autumnalis*." If it occur in small-pox, it is called "*roseola variolosa*;" if in cow-pock, "*roseola vaccina*." It has various names, according to these circumstances; which names it is unnecessary to remember. Occasionally we see such rosy patches in continued fever; but still it is called "*roseola*." The redness of the skin observed in gout, is also called "*roseola*;" and the redness of the skin sometimes observed in rheumatism, especially of the fingers, bears the same name. Occasionally the mucous membrane of the throat, more particularly of the pharynx, suffers the same degree of redness. It would appear that, occasionally, something of the same nature occurs in the stomach and intestines. At least when there is this eruption of the body, there will be a violent degree of heat in various parts of the abdomen. After inoculation for small-pox, this little redness will sometimes take place before the pustules appear. This is said to have happened in one out of fifteen cases; and inoculators used to imagine, that it betokened a mild form of the disease; while, if the redness was general and deep, and there was much pyrexia, they supposed it indicated that the disease would be severe,—would be confluent.<sup>a</sup> The roseola which occurs in cow-pock, generally appears on the eighth or ninth day.

*Treatment.*—This disease requires no treatment whatever; unless it be thought right to lower the child's diet, and give it a dose of physic. The great importance of knowing this rash, is not for the sake of curing it, but in order to distinguish it from another disease; for many children have been said to labour under measles, or scarlet-fever, when they have only had this redness of the skin. We hear of children having had measles, or scarlet-fever, half a dozen times; whereas they had merely this little redness of the skin, called "*roseola*" (or "*rose-rash*.")

## SECTION II.—ERYTHEMA.

*Identical with Roseola.*—The next disease is, by some writers, separated from roseola, and is called "*erythema*." It is said to consist of red patches or diffused redness. It often affects the subcutaneous tissue; so that there is a slight swelling. To show the absurdity of separating these two diseases, I may mention that one is called "red patches, variously figured and irregularly diffused;" and the other is called "red patches, or diffused redness." I am sure it is frequently impossible to distinguish between these two diseases. The different varieties of erythema are much more unlike each other, than many cases of erythema and roseola. All that we have to remember is, that a little redness is called either "*roseola*" or "*erythema*;" that roseola occurs particularly in infants; and that erythema<sup>b</sup> occurs sometimes in rather a severe form.

*Varieties.*—Erythema may be transient, and last only about a week; and then there is furfuraceous (branny) desquamation. Sometimes it is local, arising from friction; and then it is called "*erythema intertrigo*." If the skin in the groin or arm-pits be irritated, the motion of the parts increases the irritation; and if they be accidentally irritated by the dress, then the redness will increase; and this is sometimes called "*intertrigo*." However, when this redness is slight, it is called "*ery-*

<sup>a</sup> Rayer entertains a different opinion.

<sup>b</sup> Sometimes called "red-rash."

thema *fugax*." If the skin be very smooth, it is called "*erythema læve*." If it have a distinct margin, it is named "*erythema marginatum*." If there be small papulæ, it is designated "*erythema papulatum*." If, instead of papulæ, we have slightly elevated tubercles, it is called "*erythema tuberculatum*." If we have large bumps, it is then designated "*erythema nodosum*."

*Causes*.—[Rayer has primarily divided erythema into "idiopathic," and "symptomatic;"—divisions far more comprehensive and practical in their nature, than those proposed by Willan; who has classified *appearances*, rather than *causes*. Idiopathic or local erythema ("intertrigo") generally arises from some obvious cause of irritation;—such as friction, pressure, distension of the integuments, extremes of heat or cold, the stings of insects, chemical irritants, or the presence of various eruptive diseases, wounds, or ulcers. Symptomatic erythema, which embraces six of Willan's varieties, is contingent on and associated with various inflammatory affections (especially those of mucous membranes,) continued fever, dysentery, and other affections.]<sup>a</sup>

*Accompanying Signs*.—This disease is now and then preceded by a little illness, which disappears when the eruption occurs; and now and then there may be a little feverishness during the attack; but, for the most part, it is a trifling complaint, or is consequent upon some other affection. Rayer considers, that when there is an internal affection, the disease is the sympathetic effect of the internal irritation;—that an irritation of the stomach or intestines is the real cause of the disease; and not that this disease itself is at all capable of affecting the constitution. When persons are out of health, there will be an external inflammation, not attended with any secretion; and that inflammation is called "erythema."

*Erythema Nodosum*.—But there is a form of this disease which is very obstinate. It appears in great patches, chiefly on the legs, and particularly in females. If we draw our fingers along the legs, we find very hard and red bumps. It is called (as I before said) "*erythema nodosum*." We are frequently consulted respecting it, and asked to give it a name; and if we cannot, we are considered deficient in skill. Patients place the more confidence in the physician, if they fancy he knows what is the matter with them; and it is very natural that they should do so. It is very easily cured, if treated properly at first; but if it be neglected, it is a very obstinate affection. Now and then, instead of bumps, we have tubercles (in the common acceptance of the word;) and then the affection is called "*erythema tuberculatum*." The tubercles are like peas. This variety is worth knowing; because patients frequently die when they have it, though I do not know that they die of it.

*Treatment*.—The best treatment for this disease, is anti-inflammatory;—in fact, just the same as for all the others that I have mentioned. If the patient's strength will bear it, we may take away blood with advantage; and generally it is bled and cupped. It is proper also to purge the patient. In fact, we may treat him on the antiphlogistic plan; either purge him alone, or bleed him at the arm as well. If there be anasarca of the legs, we may favour its removal by the recumbent posture. We cannot expect the erythema to disappear, while the leg is hanging down, as it arises from the distension of the part; and if the distension of the part be allowed to remain, nothing will remove the erythema. The general rule, however, is to treat erythema as we should any other inflammation. In the erythema which occurs in the legs of females, we shall derive very great benefit from these measures;—that is to say, bleeding in the arm, the application of leeches to the neighbourhood of the part, and active purging; but we shall derive more benefit from colchicum than from any thing else. I have had great experience in the treatment of this disease; and I know the comparative efficacy of combating it by purging with common cathartics, and by purging with colchicum. I find that col-

<sup>a</sup> "Cyclopædia of Practical Medicine;" Article "Erythema;" Volume 2; Pages 115 and 119.

<sup>b</sup> These forms of the disease are very accurately delineated in Plates 31 and 32 of Willan's work.

chicum is the best medicine that can be employed, not only in severe prurigo, but also in this species of erythema.

*Erythema Tuberculatum*.—I mentioned that, in one variety of this affection, there was great redness of the skin, with hard lumps;—not so large as in “*erythema nodosum*,” but small lumps about the size of peas, or small-pox pustules. This is a state of the parts which I have never seen but once; and then I confounded it with “*erythema nodosum*,” and thought nothing of it;—imagining that I could cure it. The lumps had no sooner disappeared, than the man became paralytic, then hectic; and died in an extraordinary way, with symptoms of various diseases. I was not then sufficiently aware of the distinction between “*erythema nodosum*,” (which is an innocent disease,) and “*erythema tuberculatum*,” but Dr. Willan says, that he had seen only three cases of “*erythema tuberculatum*,” and all of them proved fatal.<sup>a</sup> Two of his patients died of hectic,—just as mine did; and one died of subsequent hydrocephalus. My patient died hectic; and if he was not hydrocephalic, he had affection within the brain; for he was paralytic. Dr. Bateman says that he never saw the affection. The treatment, I presume, would be the same as for “*erythema nodosum*,”—bleeding to a certain extent, and colchicum. I gave it to this man; but, to my astonishment, he did not get well. It is not the erythema that gives rise to paralysis or hectic; but (I presume) it takes place only in constitutions which are strongly disposed to some internal disease, and when the patient is on the eve of labouring under it.

### SECTION III.—URTICARIA.

The next of those diseases in which the inflammation is extended in patches over the skin, is “urticaria.” I select it as the next because it is not a *contagious* disease; and, indeed, is almost always a disease free from danger;—just like the three I spoke of in the class of papulæ,—namely, strophulus,<sup>b</sup> lichen,<sup>c</sup> and prurigo;<sup>d</sup> and just like the two of which I have already spoken in this class,—roseola<sup>e</sup> and erythema;<sup>f</sup> except “*erythema tuberculatum*,” which, although it will not itself prove fatal, occurs in persons who usually soon die of something else.

*Characters of the Eruption*.—This disease, urticaria, is (in plain English) the “nettle rash.” It is so called because the appearance is precisely that of a person stung with nettles;—“*urtica*” being the Latin for “nettle.” It is described by some writers under the term “*essera*,” which, I understand, is the Arabic name. Dr. Heberden (I think) speaks of nettle-rash under that title. In this disease there are “efflorescences” (as they are called),—extended patches; but besides that there are wheals. I need not say that a wheal is a pretty hard elevation of the skin; such as occurs from a horse-whip applied to the surface of the body;—but it is defined particularly, by Dr. Willan,<sup>g</sup> to be a “round, oval, or longitudinal elevation of the *cuticle*.” One ought to comprise more in it than that, however. We might say, in general terms,—“a round, oval, or longitudinal elevation of the *skin*,” but still we must add—“not permanent; not containing fluid; and not tending to suppuration.” Of course, if the *cuticle* be raised (according to Dr. Willan’s expression), there must be something under it. One would imagine there must be a vesicle, water, or pus; it is, therefore, improper to say,—“elevation of the *cuticle*.” The *cuticle* is raised; but it would be wrong to say,—that the *cuticle* is raised from the other component parts of the skin. The cellular membrane indeed is raised, as well as the cutis; and there is a hard bump, and an extended efflorescence (or patch) around the bumps. This efflorescence is of a vivid red,—a very *intense* red;—sometimes really of a *damask* hue; almost the

<sup>a</sup> See Dr. Willan’s “Description and Treatment of Cutaneous Diseases,” Order 3; Genus 4; Species 5.

<sup>b</sup> See Page 367.

<sup>c</sup> See Page 369.

<sup>d</sup> See Page 370.

<sup>e</sup> See Page 374.

<sup>f</sup> See Page 375.

<sup>g</sup> In his “Description and Treatment of Cutaneous Diseases,” Order 3; Genus 3.

appearance which we observe in those persons said to have "claret marks." Occasionally there are a few very small wheals, but not always;—the *efflorescence* being the character of the disease; though, in the greater number of cases, in the midst of this efflorescence, we find these wheals; which appear white in the midst of the red patches. There is an extreme itching;—that sort of itching which is called "tingling;" exactly as if a person were stung with nettles. To the eye of a bystander, and to the feelings of the patient, the state is just that of a person stung with nettles.<sup>a</sup>

*Varieties.*—If the bumps be very hard indeed, they are, at the same time, large; and that variety of the disease is called "*urticaria tuberosa*." It is sufficient to remember, that sometimes the bumps are pretty large and hard, and very painful. This variety chiefly occurs in the loins and legs, and is generally worse at night; subsiding in the morning, and leaving the patient weak. If it happens that these wheals and patches are numerous, and of irregular form, and coalesce, it is called "*urticaria conferta*;" and these are said to occur chiefly in persons of a dry, swarthy skin, above forty years of age. If the disease has been preceded or is accompanied by headache, nausea, gastrodynia, drowsiness, and pyrexia, it is called "*urticaria febrilis*." Very frequently, whether preceded by these symptoms or not, it is attended by them when it does appear. If they precede it, they will still continue; but frequently they will come on only when it appears. Generally, in severe cases, there is heat and thirst. The tongue is white, yellowish, and loaded; the epigastrium is tender; the pulse is full and quick; and now and then the disease will come on, like any other inflammation, with shivering. Now and then the internal symptoms, which occur before the eruption, are relieved by its appearance; or, at least, are diminished, or disappear; but they reappear when it ceases again. Frequently, however, these will all exist together;—the internal symptoms (feverishness); and the external symptoms (efflorescence and wheals).

Sometimes the disease is chronic; and is called "*urticaria perstans*." It is sufficient to remember that urticaria may be a chronic disease. The redness will go; but the wheals, perhaps, will remain. Now and then, instead of remaining chronic, it comes and goes for many months;—vanishing and recurring; and then it is called "*urticaria evanida*." But it is unnecessary to remember these expressions. It is sufficient to know that it comes and goes, or stays;—without knowing how authors arbitrarily choose to designate these varieties. Dr. Bateman says there is no pyrexia; but I know that there frequently is; and also an inflammatory state of the head and of the abdomen. It sometimes happens that the eruption disappears, or only comes from time to time; and when the tingling comes between the appearances of the disease, it is then called "*urticaria subcutanea*." It is, perhaps, difficult to imagine a disease of the skin to be *under* the skin; but so it is called. It lies underneath; and teases the patient without showing its face.

*Attendant Symptoms.*—This disease is sometimes so active, that persons can hardly see out of their eyes; and, in fact, we can see but little of their eyes. Every part around is swollen;—the cheeks, lips, and scalp are tense,—the nose among the rest. The eruption will vary in intensity, and vary in situation, not only on different days, but at different hours of the same day; it will come and go several times in the twenty-four hours. Warmth will aggravate it; and, on the other hand, exposure to cold will do just the same. When a person undresses, and there is an application of cold air to a part of the surface which before was covered, it will frequently bring out the rash, and make it worse. On the other hand, if a person go into the other extreme;—if he stand near the fire, or take stimuli, he will be worse. Rubbing and scratching make things a great deal worse; but people will do so; and, on account of the pain, they really can hardly help it. This disease is often not confined to the surface. It affects the internal mucous membranes next the sur-

<sup>a</sup> The appearance of this affection is well shown in Plate 25 of Willan's work. It is sometimes mistaken for measles or erysipelas; and therefore its characters should be studied with great attention.

face; and the submucous cellular membrane. We often find the tongue, fauces, and throat swollen;—so that the patient can perhaps hardly swallow. The irritation of the mucous membrane, in the upper part of the throat, sometimes occasions a degree of cough. I have frequently seen patients unable to swallow, and nearly unable to breathe. It is said (though I have never seen it) that, now and then, there is an irritation of the bladder, producing strangury; and sometimes diarrhœa is induced. The internal affection, in this complaint, is sometimes said to end fatally; but I presume this internal affection does not arise from the eruption. On the contrary, I imagine that it is the *general state* which gives rise to the *eruption*. The disease will last for a few days, perhaps a fortnight; and now and then there is a slight scurf afterwards. The cuticle, in consequence of the irritation, is separated from the parts beneath, and comes off in the form of slight scurf. This occurrence, however, is not general.

*Causes of Urticaria.*—I believe that the most frequent cause of urticaria is the application of cold; especially when the body is heated. It will frequently arise from cold applied to the surface;—sometimes cold and wet; but especially when the body is over-heated. It is, perhaps, sometimes induced by sudden heat. It will frequently arise from an emotion of the mind, from teething, and from certain ingesta. Some have it through *one* kind of food; and some through *another*. In some persons, almonds will occasion it; or rather the *skin* of almonds. It is not the *blanched* almonds that cause it, but the *unblanched*;—so that it is the *external part* that produces the disease; and this it does in consequence of the skin of the almond containing hydrocyanic acid. The latter, in its medicinal form, will now and then have the same effect. Various kernels of fruit will give origin to it, in some people;—in consequence of containing the same substance. Mushrooms, also, will sometimes occasion it. I suppose the mushrooms must be of peculiar kinds. Herrings, particularly “*red herrings*,” and shrimps, will likewise occasion it. Shell-fish are very often the cause of the disease; but I believe muscles produce it more frequently than other kinds. We hear of persons being poisoned with muscles; and they are said to swell. I imagine the idea of swelling from being poisoned, arises from this circumstance;—that urticaria is produced by different substances; and, when it is produced, the face often swells prodigiously, and sometimes even the whole body; and if persons have previously eaten muscles, they are sure to say they are poisoned; but it hardly amounts to that. So intense is the idiosyncrasy of some persons, as to muscles, in reference to this disease, that a gentleman mentioned to me the case of a woman, in whom urticaria was induced by one tea-spoonful of the water in which muscles had been boiled. She always had urticaria if she tasted muscles; but, having boiled some for her husband, and being extremely fond of them, she thought she might indulge herself with a little taste of them; and so she took a tea-spoonful only of the liquor; but it had the same effect as if she had partaken of the muscles. Crab-soup, which (I suppose) is much the same as the liquor in which muscles are boiled, will also induce the disease. Malt-liquor, white-wine-vinegar, and common spirits, will, in some people, produce it. A medical man told me, that his wife always had it if she took gruel. One of the most common causes, among medical agents, is *copaiba*. Many persons, on taking *copaiba*, are covered with nettle-rash. I had a patient in whom it was produced, in the greatest intensity, I ever saw it, by the sulphate of quinine. I never knew this before. His eyes were closed; his face was so swollen, that his friends did not know him; he was in a most intense burning heat; and could scarcely breathe. Swallowing was impossible. His brother came to me, and told me of the circumstance. I wished to ascertain whether it was the sulphate of quinine; and I begged him to take only a grain. He complied with my request, and it had the same effect, only in a less degree. He then took a minute *fraction* of a grain. There was not more quinine than (as is sometimes said) was “sufficient to swear by;” and even that produced a degree of uneasiness in his throat, and a certain tingling in his skin. I have known several persons, in whom the disease has been induced by *laudanum*;—in fact, by opium in any common form.

I mentioned<sup>a</sup> that, in my own case, whenever I take opium, I am sure, in two or three hours to have an itching of my nose; which will not leave me quiet for several hours. The same substance, in other persons, will induce universal tingling of the skin, with bumps;—in fact, nettle-rash. Pepper, and various spices, will have the same effect. Pepper and vinegar occasion in me a great itching of the scalp. I once saw the disease induced, very violently, by a mixture of subcarbonate of iron with treacle: whether it was the iron or the treacle, I do not know.

External stimuli will induce it; and it may spread along the skin, so as to prevail to a considerable extent. Dr. Willan says<sup>b</sup> he knew a person, in whom it was produced by a slight application of Unguentum Hydrargyri; and another who had it from rubbing the hands with oatmeal. It is worth notice that, when an irritant is applied to the skin, the effect is not always limited to the spot; but other parts, either around, or *to* some distance, or *at* some distance, may suffer. Croton-oil often causes redness and vesicles, far beyond the spot of application. Tartar-emetie, applied to the legs, often causes pustules in the genitals.<sup>c</sup>

*Treatment.*—With regard to the mode of treatment, the shortest way, if the patient's strength will bear it, is to take blood from the arm. Even if any thing improper has been taken into the stomach, bleeding in the arm produces almost instantaneous relief; and the patient will speedily get rid of the complaint. A friend of mine was taking copaiba, in consequence of his misdeeds; and next day, was seized with an eruption all over his body. His face was swollen and burning; and his lips were so stiff, that he could scarcely move them to eat. The aperture of his eyelids became very small; his pulse was about 100, and full; he was in a great heat, and red all over. Before I saw him, he had taken an emetic to empty his stomach; but it was quite in vain. The copaiba had entered his system; and was there causing irritation. When I went to him, I immediately saw it was nettle-rash; and begged another friend, who was by, to put a lancet into his arm, and detract a quantity of blood. Before the basin was half filled, he felt relief; and as the blood continued to flow, he felt more and more benefit. He became paler and paler; the swelling of his face declined; and before evening he was tolerably well. He took a dose of physic to assist the bleeding; but I dare say he would have done without it. The venesection, notwithstanding the emetic had been fruitless, instantly relieved him. A short time afterwards, he found it necessary still to go on with the copaiba;—his other troubles not having ceased; and the same effect was again produced. He took no emetic that time, but was again bled; and the disease instantly disappeared. He had no further trouble.

*Evacuants.*—However, if we are sure that the cause is still in the stomach, in consequence of the short time which has elapsed since it was taken, it would be but common sense to empty it; but I confess, if the person were of a full habit, I should take away blood first; for we shall find that a most speedy mode of cure. We must, as in all other inflammatory complaints, regard the constitution of the patient on the one hand, and the intensity of the disease on the other. If we take away blood, we shall cure the disease in perhaps a twentieth part of the time that will be required, if we trust to low diet and purgatives. I would, in every case, back bleeding by low diet and purging. In the chronic form of the disease, the patient should avoid stimuli, and adopt the antiphlogistic regimen. He should avoid eating any thing that can excite either his body or his mind; and if the pulse be strong, he should unquestionably lose a small quantity of blood. The warm-bath is said to relieve the affection; and in some cases bathing has done good. Bark and acids are praised. All the cases, however, that I have seen, whether acute or chronic, have been best and most successfully treated by venesection, and

<sup>a</sup> See Page 373.

<sup>b</sup> In his "Description and Treatment of Cutaneous Diseases;" Order 3; Genus 3; Species 2.

<sup>c</sup> For this fact I beg to refer to a paper of mine, on Subcarbonate of Iron, in the thirteenth volume of the "Medico-Chirurgical Transactions." (Page 241.)

common antiphlogistic measures. In the case of the lady who had urticaria from taking the subcarbonate of iron in treacle,<sup>a</sup> for a couple of days, the eruption began one Sunday morning; and it was supposed that she had got scarlet-fever. The eruption was of a damask-red colour, with bumps; and it came out suddenly. She was in the greatest agony. Her countenance expressed great distress; but, though I imagined it arose from the medicine, I did not give her an emetic. I had her bled; and while her noble blood flowed (for she was a peeress) the symptoms declined; and when the arm was tied up, there was no redness to be seen. No pains were taken to get rid of the offending matter; which, in all probability, was the cause of the disease. I did not know the use of bleeding, in this complaint, when I began practice. But, finding it mentioned by several authors, it seemed rational; and I adopted it in every case afterwards, where the pulse would allow it.

*Treatment of the Chronic Form.*—In the chronic form, if we find any other disease be present, we must endeavour to remove that. The urticaria may arise from chronic enteritis or gastritis; and that ought to be remedied in the usual way; which usual way is to apply leeches to the abdomen, or adopt general bleeding, &c. We may get great and deserved credit for curing this disease; which is sometimes very obstinate. The secret of the cure generally lies in bleeding, and adopting antiphlogistic means. Among local applications, the chlorides, prussic acid, or nitric acid, best alleviate the itching.

#### SECTION IV.—RUBEOLA.

*Various Names and Derivations.*—The next disease of which I shall speak, is “measles;”—a severe affection, which is frequently fatal. It is called, among the medical men in this country, “morbilli,” or “rubeola.” We have adopted the expression “*morbilli*” from the Italians; who so named the disease from its being a less kind of plague;—the “minor plague,”—the “little disease.” The expression “*rubeola*” was formerly applied to scarlet-fever and measles in common; as well as to other diseases. In fact, it was Sauvages (the first writer on Methodical Nosology) that restricted the term “*rubeola*” to *measles*. The word “*rubio*” (“red”), from which it comes, is Spanish; and it was written “*rubiolo*,” as it is pronounced;—the accent being placed on the *o*.

*Its Nature.*—This is a contagious and infectious disease, chiefly affecting children; and is more severe in them than in adults. There is very rarely an indisposition to it; for we seldom meet with any one that will not take it. The indisposition is less frequent than the indisposition to small-pox. It rarely occurs more than once; but sometimes it does. Dr. Baillie<sup>b</sup> describes eight cases of its occurrence more than once. When it does occur more than once, it generally prevails as an epidemic disease.<sup>c</sup> It chiefly prevails in winter and spring. It is very well characterized;—having very peculiar symptoms, which hardly any one (I think) can mistake.<sup>d</sup>

*Progress of the Disease.*—It is almost always ushered in by catarrhal symp-

<sup>a</sup> See Page 380.

<sup>b</sup> In the “Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge.”

<sup>c</sup> By “epidemic,” I do not mean *contagious*. The word “*epidemic*” has been attempted to be restricted to those diseases which prevail over a number of persons, without any contagion in the atmosphere; but the word relates to diseases that prevail temporarily over many people, without a local cause,—be it contagious or not contagious.

<sup>d</sup> Dr. Montgomery (in the “Cyclopædia of Practical Medicine”) gives the following clear and concise definition of rubeola:—“A contagious inflammatory disease, affecting at once the skin and gastro-pulmonary mucous membrane; in which, after catarrhal fever has continued about three days, a rash appears on the skin, at first in small stigmatized dots, not unlike flea-bites; which, presently coalescing, form patches of a crescentic or semilunar form; first on the face, and thence spreading gradually downwards over the whole of the body and limbs, at the end of four days disappear by desquamation of the cuticle.” (Volume 3; Page 625.)

toms;—that is, by flushing of the face, redness of the eyes, heaviness of the countenance, a “running of the eyes and nose, soreness of the throat, sneezing, and a hoarse and sounding cough;—a cough which old women, who have been much amongst children, describe as the “measle-cough.” I cannot describe it. I can only say it is a *hoarse* cough.

These catarrhal symptoms will sometimes last *two* days, and sometimes *twenty*, before the cutaneous affection shows itself. But, in general, it appears on the *fourth* day;—sometimes as early as the *third*, sometimes on the *fifth*, and sometimes on the *sixth*. It is generally upon the face that the cutaneous affection presents itself. It appears as a rash on the forehead and the chin; and thence it spreads all over the face. The next morning it is found to have spread, not only over the face, but over the breast and trunk, and upon the extremities. On the fifth day, the disease has pretty well covered the body; and it is on that day that it is most vivid on the face. On the sixth day, the eruption is pale on the face, and most vivid on the body; and on the seventh day, it begins to disappear in the latter situation. The disease altogether is of about seven days’ duration. The catarrhal symptoms appear for four days; upon the fourth day the cutaneous disease appears; and this lasts three days;—making seven altogether. But, now and then, children have catarrh for two or three weeks; and then, in the midst of the catarrh, without any previous additional symptoms, except perhaps an increased intensity, the cutaneous disease shows itself. Now and then, there are, on the back of the hand, patches, which did not appear before the sixth or seventh day of the fever; and, in the remote parts of the body, the redness occasionally does not come on till that time; and then the eruption in these situations does not decline, perhaps, till the eighth day. On the ninth day, there is only a slight discoloration left;—a sort of brownish appearance. The colour, in this disease, is by no means so vivid as in roseola, and as in scarlet-fever. When it subsides, if the inflammation have been pretty extensive, there is a furfuraceous desquamation. This, then, is the course of the disease.

The longer the premonitory symptoms and the general indisposition occur, before the appearance of the eruption, and the more severe they are, the more severe, generally speaking, will be the disease itself. The affection, too, is usually more severe in the *cold* than in the *warm* months. Sometimes, in the severe form of the disease, there are, about the fourth day, small dark patches in the mouth, on the hard and soft palate, upon the tonsils, and upon the uvula;—the mucous membrane being affected, as well as the skin.

*Characters of the Eruption.*—When the affection first appears, there are only (at the utmost) little red dots, nearly circular; which are scarcely perceptible, and rather less than the spots of flea-bites. They become more and more numerous, however; and coalesce into patches. All the exanthemata begin and extend in this way. The patches which are formed in this disease, are of an irregular figure; and frequently assume a semicircular or crescentic form. This is characteristic of the disease, and is worthy of notice;—not that the diagnosis is often at all difficult; but, if it *be* difficult, we may be assisted by remembering, that the patches in measles affect a semicircular or crescent-form; that, in the midst of these patches, there are circular spots; and that, around the patches, are spaces of the natural colour. The disease is most severe upon the face. The skin of the face is finer, and more abundant in red vessels, than that of many other parts; and there it is that the effects of inflammation are most severe,—from these circumstances. The skin is not smooth, but roughened; so that, by passing the finger along it, a little roughness is observed;—hardly worth the name of *roughness*, perhaps; but an *inequality*. Occasionally, if the inflammation be severe, this is observed in other parts of the body. Occasionally the red dots are more or less hard and elevated. Although the disease is characterized by patches, the inflammation may be so intense as to cause the face to swell, and the eyes to be closed; nay, the symptoms may be so severe as to cause little collections of water, the size of millet-seeds, which are called “miliary vesicles;” and sometimes there are papulæ on the hands,

wrists, and fingers;—elevations of the cuticle, having a distinct roughness, in the midst of the patches; so that while the patches give to the feel a sensation of being elevated above the surrounding skin, in the midst of these there will be another roughness, arising from the papulæ.

*Diagnosis.*—When we hear a child sneeze and cough, and see these crescentic semicircular patches, we may be sure it is the measles. It is on the face we usually see the disease best characterized. We may mistake it on the arms, hands, and body; but we can hardly do so on the face. It is very important to make a correct diagnosis here, although the disease may be of a slight character; because the man that tells a parent that the child is about to have the small-pox, when it is going to have the measles, will of course be deemed ignorant. Sometimes the spots will go down as fast as they appear.

*Continuance of the Catarrhal Symptoms.*—It is almost constantly observed, in this disease, that the catarrhal symptoms are not much lessened on the appearance of the eruption. It is often said by authors, that when the eruption comes out, in cutaneous diseases, the internal symptoms are relieved. We all meet with this occasionally; but, in a great number of cutaneous diseases, I have seen the internal symptoms not alleviated by the appearance of the external. In measles, however, it is a well-known fact, that, so far from there being an alleviation of the internal symptoms, they are more frequently aggravated than not; at any rate, in general, they are not mitigated. When the eruption comes out, the catarrh is confined perhaps to the bronchia. It appears that the catarrh is more or less bronchitic; for there is an affection of the superior parts of those tubes. But frequently the irritation of that part of the membrane below the larynx increases; so that we have decided bronchitis. Sometimes there is an affection of the substance of the lungs (pneumonia); and sometimes of the investing membrane (pleuritis).

*Sequelæ.*—Frequently, when the measles are over, they leave chronic bronchitis, chronic pneumonia, chronic pleuritis, or even phthisis. They frequently seem to give rise to tubercles. Frequently, too, there is left after measles a chronic diarrhœa (generally of an inflammatory character); frequently inflammation of the eyes (ophthalmia); ear-ache; running of the ears (otorrhœa); deafness. Frequently there is disease of the mesenteric glands; and frequently, after the disease, we see various chronic cutaneous affections; such as ecthyma, rupia, porrigo, boils, aphthæ, &c.\* In fact, there is no end to the mischiefs that measles leave behind. They may recede suddenly; and then we may have internal inflammation of the lungs, or within the abdomen, or in the head; but it is chiefly in the chest that inflammation occurs, when the disease recedes. It is not by any means certain, that the retrocession of the measles causes these symptoms. It is just as probable that, in many instances, the occurrence of the internal disease puts a stop to the external. It is a great mistake to suppose, that the retrocession of an eruption causes internal disease, in every case where such internal disease occurs. There can be no doubt that the occurrence of another disease, in the *internal* part of the body, will put a stop to, or suspend, a disease which has previously been going on in an *external* part; but it is a fact that, when measles suddenly disappear externally, for the most part there is some internal affection.

*Predisposing Causes; Age.*—Infants, or at least children, are considered to be much more susceptible of the disease than adults; but infants at the breast are certainly not so susceptible of it as others. It is not at all an uncommon thing to

\* Dr. Montgomery ("Cyclopædia of Practical Medicine") says,—“In a few instances, gangrene of the inside of the cheeks, gums, and lips has been observed; in other instances, mortification has affected the uvula. Anasarca has been known to appear after measles, as it very often does after scarlatina; but this is so rare an occurrence, that where it does occur there is much reason to suspect, that the previous disease has been scarlatina. Dr. Harty, who has had extensive opportunities of observing this disease, informed the writer, that he has very frequently found, during convalescence from measles, that the pulse became unusually slow (about forty or fifty in the minute); but it did not appear to be connected with any thing unfavourable in the condition of the patient, whose recovery was uninterrupted.” (Volume 3; Page 631.)

notice the disease in a family of children; all of whom have it, excepting one which is at the breast. There is no doubt that *extreme* infancy is not so disposed to the disease, as *later periods* of infancy. It is considered, however, that infancy at large, childhood, and the young adult period, are more subject to it than the *full* adult period; and much more so than old age. In considering this question, we ought to reflect on the circumstance, that although fewer adults have it than children, yet it is a disease that occurs generally but once; and it is possible that the reason why it is not seen in adults is, that almost all adults have had it when children. To ascertain the fact fully, we ought to have a number of *adults* who never had the disease; and expose them with an equal number of *children* who never had the disease; and see how many of each are affected. But even if a smaller number of adults escaped than of children, still that might not be satisfactory; because those adults probably did not have the disease in infancy,—owing to a positive indisposition; and that indisposition might still prevent them from taking it. We can draw no inference from the number of persons who have the disease in childhood; as is usually the case. Dr. Babington, I have heard say, has seen measles occur after sixty years of age; and it is a fact that we may see small-pox after seventy. Some children are said to have been born with measles;<sup>a</sup> and others have had it at a very short period after birth; but, as a general rule, the extremes of age are very unfavourable to this affection.

*Exciting Cause.*—The exciting cause of the disease is, indisputably, a peculiar contagion; and this has been communicated by art;—the disease has been conveyed by inoculation. Experiments of this kind were made, many years ago, by Dr. Home,<sup>b</sup> Professor of Materia Medica in the University of Edinburgh. Many have thought but little of these experiments; but, in 1822, an Italian physician (Dr. Speranza) in the territory of Mantua, repeated them. He inoculated six cases, and afterwards himself, with the blood taken from a slight scratch in a vivid papula. In a few days the measles appeared; and went through their course mildly and regularly. This encouraged him to make further experiments; and he says they were all successful. Occasionally the measles do produce little vesicles; and it is certainly likely that these vesicles contain the contagious matter in a concentrated form. Many who have attempted to inoculate for measles have failed; but that measles have been communicated by inoculation, there can be no doubt, and as the disease, when produced naturally, is so severe; while it is slight when produced artificially; and as most children have the disease, I think it a pity the subject has not been more attended to. There is not the same facility of producing this disease, as small-pox; but it is possible to communicate it; and there can be no harm in scratching a few children, and attempting to give them the measles, during the favourable period of the year. Nor do I see why, as most children have it, they should not be exposed to the contagion, by having the clothes of others labouring under measles placed near them, during the warm summer months.

*Period of its Occurrence after Exposure.*—With regard to the time at which the disease occurs after exposure, Willan says that he knew a person who had had the measles, and became convalescent; and his clothes infected a child in the country; and that the child had the eruption sixteen days after being first exposed. I suppose the usual period is from five days to a fortnight; but most probably this varies, as in most other contagious diseases.

*Varieties.*—1. *Rubeola sine Catarrho.*—The measles sometimes occur, without any internal affection;—without any catarrhal symptoms, running of the eyes or nose, sneezing, heaviness of the head, or cough; and it is said, that when disease

<sup>a</sup> "It is asserted by Rosen, Vogel, and others, that infants have been born with the traces of measles. Guersent ("Dictionnaire de Medicine," Tome 18, Page 513) mentions having seen an infant born with measles on it (having taken the disease from the mother); but, we presume, such instances must be of exceedingly rare occurrence."—"Cyclopadia of Practical Medicine," Volume 3, Page 625.

<sup>b</sup> "Clinical Facts and Experiments," published in the year 1758. He was the father of the present Edinburgh Professor.

occurs in this exceedingly mild form, it does not prevent a second attack. This was mentioned by Dr. Willan;<sup>a</sup> and, as an accurate observer, he was, perhaps, never surpassed; but Rayer declares that this kind of disease is not measles at all, but only roseola. Dr. Willan,<sup>a</sup> however, says that he saw two distinct cases of measles,—indisputable measles, without any catarrh; and I myself attended a family, in which several of the children had had the measles, with catarrh; and one of them had, at the same time, an eruption exactly like the others, but without catarrh; and which was pronounced, by the medical attendant, to be the measles. The rest of the family never had the disease again; but this one, a year afterwards, had regular measles. From this fact, occurring within my own knowledge, I cannot but think that Willan is right. If any could distinguish between rubeola and roseola, it must have been Dr. Willan. Besides, all contagious diseases will occur in an imperfect form. The most intense contagious disease may be of unusual shortness, or of unusual mildness, or both; and may even want some of its symptoms. Pustules of small-pox sometimes occur without any indisposition. Doubtless, measles is no exception to the general truth. When small-pox has so appeared, Willan<sup>a</sup> says it may begin regularly, and be perfected on the eighth or ninth day from the first appearance of the pustules, *without indisposition*. In the same manner, measles will sometimes appear, and proceed to perfection in a few days after the eruption, *without catarrh*. It is well, therefore, to tell the parents, that the child may have an attack again; for a second attack of measles is possible in any case; but if they occur without catarrh, it is almost certain that the patient will have them again.

2. *Rubeola Nigra*.—The measles are sometimes attended with a darkness of the skin. About the seventh or eighth day, the rash suddenly becomes yellow, or livid. There is languor or quickness of the pulse; but no inconvenience arises; and the whole ceases in a week or two. It does not appear that there is any danger from the mere lividness of the patches in this disease. Many eruptions of the skin, when they subside, become of a dingy or yellow colour, without any danger whatever. There is merely a little change of colour, which is quite independent of the present indisposition. So it happens in measles. The dinginess is more intense than usual; the part becomes exceedingly brown and yellow; but this generally ceases after a week or two. Perhaps the blood is in a state approaching to stagnation;—the circulation not going on in the natural way. This species is called "*rubeola nigra*."<sup>b</sup>

3. *Rubeola Putrida*.—But it is said that measles sometimes do occur in a really typhoid state of the body;—that "putrid measles" take place. Sir William Watson, who was physician to the Foundling Hospital, said that he saw this sixty years ago. Others think this was an error: because (like Morton, a cotemporary of Sydenham) he did not distinguish measles from scarlatina; and proposed to banish the latter word as superfluous. Indeed, the original writers on measles all consider it and small-pox as the same disease in different forms. Dr. A. T. Thomson, however, declares, that he saw a case in 1804, where the languor and state of the pulse were alarming; and the skin rubbed off like a moist cobweb; but the patient recovered by the use of wine and cordials. I never saw this form; but the other (*rubeola nigra*) is not very uncommon.

[The prognosis in measles, during the early stage of the disease, is always favourable; but a mild attack of the proper symptoms is often suddenly converted into a most dangerous disease. It should be recollected that the eruption, or the mere disease, rarely puts the patient's life in hazard;—as we so frequently observe in scarlatina, in which the vital powers are so alarmingly depressed by the action of the poison; but in measles, the internal inflammation, particularly of the lungs, which frequently supervenes, is the chief source of danger. It is very generally

<sup>a</sup> In his "Description and Treatment of Cutaneous Diseases," Order 3; Genus 1; Species 2. (Page 235.)

<sup>b</sup> "*Rubeola sine catarrho*," and "*Rubeola nigra*," are well represented in Plates 21 and 22 of Willan's Work.

admitted, that measles are more severe, and attended with more danger, in adults than in children. Dr. Montgomery dissents from this doctrine: and states that, as far as his experience enables him to judge, he should pronounce exactly a contrary opinion.<sup>a</sup> The most severe cases of measles which have come under our notice,<sup>b</sup> have certainly been in adults. The character of the prevailing epidemic, and the peculiar type of continued fever of the same period, should be carefully weighed in forming the prognosis, as well as in determining the treatment of measles. The season of the year has a more important influence on the issue, than in scarlatina or variola; the complaint is more likely to proceed favourably and safely in mild than in cold damp weather. When measles quickly succeed to other infantile disorders, as pertussis or remittent fever, the danger to be apprehended is greatly increased; the same may be said when it attacks children disposed to affections of the brain, or to scrofula. The following are the general circumstances which denote danger;—unusual violence of the eruptive fever, especially if attended with spasmodic twitches or convulsions; the eruption appearing late, and of dark livid colour; the supervention of thoracic or abdominal inflammation; severe headache, with nocturnal delirium; retrocession of the rash; extreme dyspnœa, coming on late in the disease, with a dusky flush on the cheeks, and livid lips; the accession of typhoid symptoms; the appearance of petechiæ, or profuse hæmorrhages from mucous surfaces.

A favourable prognosis may be pronounced when the eruption appears at the usual time, and proceeds regularly over the whole body and limbs; by the mildness of the bronchial affection; by the appearance of moderate diarrhœa; by the softness of the pulse; by the uniformly warm and moist state of the skin; and by the return of sound refreshing sleep.<sup>c</sup>

*Treatment.*—In the treatment of measles, the first point is to attend to any internal symptoms of inflammation that may exist. A large number of cases will do very well, without any medicine at all. The child cannot eat; and therefore, if not recommended by the parent, will not take any thing injurious. He is more inclined to take plain water, milk, or milk and water, than any thing else. The patient should be kept *cool*; but it is rather dangerous to keep him *cold*. He should be kept in a *moderate*, but by no means *stimulating*, temperature; for heat would do great harm, and aggravate any disposition to bronchitis; but I do not think there would be the same propriety in exposing the child to cold air, that there is in small-pox and scarlet-fever;—owing to the great disposition to bronchitis. Some have recommended the cold affusion in this disease; but the tendency to bronchitis is such, that I have never practised it, and I would not recommend it.

From the catarrhal symptoms in this disease, and their great disposition, on the appearance of the eruption, to become severe, it is always necessary to direct attention to the state of the chest;—to observe, carefully, whether there is peripneumonia, or bronchitis, or pleuritis, or any other affection of the chest; and to treat it just as if no measles were present;—to take blood from the arm or the jugular vein, or apply leeches, as the case may require. It is not requisite to pay such great attention to these symptoms before the eruption occurs; but if they be severe when the eruption comes out, blood should be taken. Leeches generally answer; but if the child be large, blood might be taken from the jugular vein, or the arm. Moderate purging is proper, and low diet. The patient must be treated on the antiphlogistic plan, according to the degree of inflammation.

*Recession of the Eruption.*—If the eruption does not come out, or recedes, we should put the patient into the warm-bath; but we must remember that this is most likely produced by some internal disease; and that internal disease, in nine cases out of ten, is inflammatory; and in eight out of that nine it is situated in the chest. The internal affection may be the consequence of the measles receding; but, in a great number of cases, it is the internal affection that puts a stop to the progress of

<sup>a</sup> "Cyclopædia of Practical Medicine;" Volume 3; Page 630.

<sup>b</sup> That of Dr. G. Burrowes.

<sup>c</sup> "Library of Medicine;" Volume 1; Page 331.

the disease on the surface. The best mode to bring out the measles again, is to lessen the internal disease. The measles will sometimes be suspended for many, many days, after appearing on the surface. They will recede in consequence of the internal inflammation; which we must subdue; and then, frequently, they will re-appear. This is a very curious circumstance. Now and then, there may not be internal inflammation. There may be mere debility; and then it is necessary to give stimulants;—ammonia and wine. When there is diarrhœa, it generally requires antiphlogistic treatment.

*Diarrhœa.*—The diarrhœa is generally troublesome, when the disease is over; but it is important, in all cases, to press upon the abdomen, and see if there be any tenderness. In a large number of cases, there is tenderness; and the diarrhœa is only to be subdued by sinapisms, leeches, &c. Sydenham pointed out that the diarrhœa was inflammatory; that opium and opiates were improper; and that venesection ought to be resorted to. Venesection is out of the question, in many cases; but it is sometimes proper. However, this is no general rule. We see cases where there is so little inflammation, that astringents and opium will cure the disease; but frequently they are not to be trusted to alone. In some we must unite this plan with the remedies for inflammation; in others we must solely treat inflammation, and the diarrhœa will cease. This is a most important point in practice, although it is simple; and unless it be carefully attended to, we may do harm when good might be effected.

Measles are very apt to leave after them an obstinate diarrhœa, which ends in disease of the mesenteric glands; and a bronchitis, that is apt to leave a disposition to the formation of tubercles. We have chronic bronchitis, and then tubercles; so that children frequently die of phthisis; but measles often set up scrofula, both in the abdomen and chest.

*Putrid Measles.*—In the putrid form of measles (which I have never witnessed), the opposite plan must, of course, be adopted; only we must take care not to mistake a blackness arising from extreme congestion of the lungs, for a putrescent state of the body. When there is congestion of the head and chest, wine and tonics would be exceedingly improper; but I should think that a careful practitioner would not make the mistake to which I have adverted.

## SECTION V.—SCARLATINA.

*Formerly Confounded with Measles.*—The next disease among the rashes of which I will speak, is scarlet-fever; which is called, in medical Latin, “scarlatina.” Till the close of the eighteenth century, this disease was confounded with measles. Morton, who (as I before observed<sup>a</sup>) was a contemporary of Sydenham, thought they were mere varieties of the same disease.<sup>b</sup> In the middle of the seventeenth century, Sennertus asks why the disease is sometimes “small-pox,” and sometimes “measles;”<sup>c</sup> and Diemerbroeck, who published in 1687, asserts that measles and small-pox differ only in degree.<sup>d</sup> Such were those days of diagnosis. In 1769, Sir William Watson did not distinguish measles from scarlet-fever.<sup>e</sup> On this account, some have affirmed that Sir William did not see the putrid form of measles;—that what he saw was putrid *scarlet-fever*; and that, as he did not distinguish between the two affections, he called it “measles.” Indeed, Morton, who confounded the disease, wished the appellation “*scarlet-fever*” to be banished altogether. He conceived that the two diseases (measles and scarlet-fever) were

<sup>a</sup> See Page 385.

<sup>b</sup> “Opera Medica; nimirum, de Phthisi; de Morbis Universalibus Acutis; de Febris Inflammatoriis. Auctore R. Morton, M. D.”

<sup>c</sup> His “Opera Omnia” were published in 1641, at Paris, in three folio volumes.

<sup>e</sup> An Account of Experiments on the Inoculation of Small-pox. By William Watson, M. D.”

but one; and he thought it a pity to use both terms;—the word “*measles*” being quite sufficient to designate the whole disease. Bateman thinks that the year 1793 was the first in which an accurate diagnosis was made. Dr. Withering published an essay on scarlet-fever, in 1788; of which essay the second edition appeared in 1793;<sup>a</sup> and Dr. Bateman considers, that the latter was the accurate date of the first correct division of these diseases. This must appear to us strange; now that the diagnosis between the two diseases is established with the most perfect facility. But so it is; and I trust that those who live a hundred years after us, will be satisfied that we were an ignorant set;—that science will so advance, as hereafter to make our knowledge appear perfect ignorance. At the present moment, people cannot settle how long cholera has existed;—whether it is a new disease or an old one. Some say that it sprung up a few years ago; and others assert that it has been known from time immemorial. It is just the same with scarlet-fever. Some say that it was not known more than two hundred years ago; that it is not mentioned in the Arabian, not to say the Greek, writers; and that it came from Africa, and broke out (for the first time in Europe) in Spain, in 1610. Willan says<sup>b</sup> it was known to the Neapolitans, before 1500, under the name of “*rossalia*,” or “*rossania*,” and that Ingrassia describes it under that name; that others called it “*rosalia*,” “*robelia*,” “*rubiola*,” “*rubeola*,” “*rubiolæ*,” and “*rubeoli*” (from “*robia*,” *madder*; and “*morbilli*,” *measles*;) and that the French used all these words for scarlatina; and, in addition, even “*rugeole*,”—terming measles “*sene-pion*.” The word “*scarlatina*” was formerly “*scarlattina*,” and is derived from “*scarlatta*,”—“a red-coloured cloth.”

*Symptoms.*—This disease is characterized by a close and diffuse scarlet-coloured efflorescence of the skin, and likewise of the mouth and fauces. There are the usual symptoms of pyrexia, for about two days; and, on the second day of the pyrexia, the eruption generally appears in some part. In the greater number of cases, I believe this is true; but occasionally the eruption will not take place till the third, fourth, fifth, or sixth day; and when the eruption does take place, it continues about five days. The interval between exposure and the appearance of the affection, is greater in adults than in children.

*Varieties.*—[There are several forms of scarlet-fever; each of which requires a separate description. The poison of scarlatina usually exhibits its effects upon two membranes; namely, on the skin and the mucous membrane of the fauces; to one or other of which, however, its action may be restricted. Hence arise the varieties of scarlet-fever;—in accordance with a well-established law of the action of other poisons,—“that they may exhaust themselves on one or more of the tissues they usually affect, without involving the whole series; and that they act with greater or less intensity, according to the peculiar idiosyncrasy of the patient.”<sup>c</sup>

In the most simple form of scarlatina, the fever is seldom of an active kind. The cutaneous efflorescence appears in the usual manner; but there is no inflammation of the mucous membrane of the throat (“*Scarlatina Simplex*”).

In the second, there is greater febrile excitement; and the general symptoms are farther complicated by inflammation of the fauces (“*Scarlatina Anginosa*”).

In the third, the symptoms are of a more severe description. The fever—which is of a typhoid type, with great depression of the vital powers—is sometimes accompanied with diphtheritis,<sup>d</sup> sometimes with gangrenous inflammation of the throat, and generally with tumefaction of the parotid and cervical glands, and acrimonious discharge from the nostrils and ears (“*Scarlatina Maligna*”).

In a fourth variety, the efflorescence does not appear upon the skin; but is confined to the mucous membrane of the mouth and throat. Although this form has not been described by Dr. Willan, as a distinct variety, it was often witnessed by

<sup>a</sup> “Account of the Scarlet-Fever and Sore-Throat; by William Withering, M. D.”

<sup>b</sup> See his “Description and Treatment of Cutaneous Diseases,” Order 3; Genus 2. (Page 289 of the First Edition.)

<sup>c</sup> Dr. R. Williams’s “Elements of Medicine,” Volume 1; Page 131.

<sup>d</sup> From  $\delta\phi\theta\epsilon\iota\varsigma$ , *skin* (or *membrane*), and “*itis*,” *inflammation*.

nim.<sup>a</sup> Dr. Tweedie, in his valuable essay on scarlatina,<sup>b</sup> has designated this variety "*Scarlatina Faucium*." Dr. Williams<sup>c</sup> has described it as "*Scarlatina sine Eruptione*."<sup>d</sup>]

1. *Scarlatina Simplex*.—In the most simple form of the disease (that called "*scarlatina simplex*") the feverishness is very moderate. On the day after the commencement of the feverishness, innumerable red spots appear on the face and neck; and these, in twenty-four hours, will spread all over the surface;—coalescing and multiplying. They thus increase and multiply; enlarging the redness, and uniting together, till they form large extensive patches over the trunk and extremities. On the third day, there is almost one diffuse and continuous efflorescence over the body; and especially around the fingers. The scarlet hue is usually most vivid on the flexures of the joints;—the skin there being very fine; and likewise on the loins. The patches are seldom universal on the trunk; but upon the extremities they are very continuous. If we turn aside the bed-clothes, we perhaps observe a continuous redness from the groin down to the foot;—the patient looking almost like a boiled lobster; and towards evening the redness is so intense, that the patient looks as if he had been smeared with raspberry-juice. On passing our finger carefully over the skin, we may find exceedingly minute asperities (resembling the "*cutis anserina*" of the cold stage of ague);—far more so than is observed in measles; but we do not observe the irregularity that occurs in measles. In measles the whole skin is raised in patches; and besides that, we frequently feel small papulæ; but, in scarlet-fever, the patches are not at all elevated. The distinction between the sensations given to the touch, in the two diseases, is very obvious.

It is usually upon the fourth day, that the eruption is at its height. On the second it comes out; and on the third it has spread all over the surface; if the lower parts were exempt before, it reaches them now; and, on the fourth, it is at its height of redness. On the fifth day it declines; and it declines by interstices;—so that the patches reappear. While the disease was increasing, the patches were lost in one continuous redness; and then, as the disease declines, the continuous redness becomes again divided into patches;—that is to say, there are intervals of paleness. On the sixth day, the eruption becomes very indistinct; and it is gone, generally, before the end of the seventh. Now and then, if the disease be severe (and sometimes when it is not) between the fourth and seventh day there are (as is sometimes observed in measles) little miliary vesicles. In acute rheumatism, also, I have seen the fingers beset with vesicles. About the eighth or ninth day, the cuticle comes off, in the form of scurfy desquamation.

The disease attacks the interior of the mouth and fauces; and it even affects the conjunctiva.<sup>e</sup> The papillæ of the tongue become enlarged; and we may see them through the white crust of dry mucus with which it is loaded. The tongue looks as if it had been slightly sprinkled with Cayenne pepper. If there be any cough, it is not that peculiar cough which I mentioned<sup>f</sup> as occurring in measles. In measles, there is a peculiarly sounding cough,—such as experienced women and nurses know to be the cough of measles; but that does not occur in scarlet-fever. If there be any cough at all, it is merely a short irritating cough; arising from irritation of the fauces, without any expectoration or hoarseness. The conjunctiva being affected, there is a redness of the eyes; but no intolerance of light, and no overflowing of the tears; and the ciliary glands are not affected.

If scarlatina be at all severe, we may have a discharge from the ears, both within

and without;—a discharge both from the Eustachian tube, and the external meatus. It may also give rise to sores behind the ears;—and to glandular suppuration in various parts; as in the parotids, and the glands of the neck. It may give rise to pulmonary disease, or to diarrhœa. It may be followed by chronic pustular diseases of the skin (called “rupia” and “echthyma”); but they are much more common after small-pox. After mild scarlet-fever, there is very often general dropsy (“anasarca”). The other symptoms which I mentioned (such as discharge from the ears, suppuration of the glands, &c.) all occur after the most *severe* forms of the disease; particularly that called “*scarlatina maligna*,” but after the *mildest* form we may have dropsy. This dropsy usually occurs at the end of the second week; and after the rash declines. It occurs particularly in spring and in autumn; and, if I be not very much mistaken, it is generally owing to the patient having caught cold, in some way or other.

2. *Scarlatina Anginosa*.—Now and then scarlatina is accompanied with little or no affection of the throat. Perhaps there may be a slight affection; though frequently it is so slight, as to deserve no notice; but if it be very obvious, the disease is called “*scarlatina anginosa*.”<sup>a</sup> There is then more violent inflammation of the fauces; which inflammation increases and decreases with the eruption; the general disease of the system, and the eruption, are altogether more intense; the heat may be 106 or even 112 degrees; and there is sickness, headache, restlessness, and delirium. The throat feels sore and straitened; and, on inspection, in various instances, a dark red line is seen along the velum, reaching down to the lower part of the uvula.<sup>b</sup> The patient is hoarse; experiences a difficulty in swallowing; and the tongue is very red, especially at the sides and the extremity. The papillæ are particularly affected; so that they are greatly increased in length.

In this more severe form of the disease, the eruption often does not appear till the third day; and very often the eruption is not so universal, but is in scattered patches; and very often it does not come out fully and remain so, but appears and disappears. Thus the whole disease is lengthened. From the eruption not coming out permanently, the disease is protracted. I mentioned<sup>c</sup> that when the measles recede, the eruption may last for some weeks. So, in scarlet-fever, if the disease comes and goes, then the period of the eruption is increased; although I do not know that it can be increased to the period to which I have seen measles extend. When the disease thus goes off, the desquamation is less regular; and, if the rash have been slight, (as it sometimes is, even when the throat is much affected,) there is perhaps no desquamation at all. Sometimes we see exfoliations of large portions of the skin, for many weeks; and these are usually upon the hands and feet. The nails have been known to crack and separate; and, now and then, superficial ulceration will take place on the tonsils. For the most part, there are shreds of viscid secretion; which are sometimes mistaken for sloughs; but they are merely vitiated secretions;—excessively thick portions of lymph. Now and then we have real sloughs; with great debility after the disease.

3. *Scarlatina Maligna*.—But we have another form of the affection; in which there is a great disposition to sloughing, to mortification of the throat, and to putrescency of the body; and this is called “*scarlatina maligna*.”<sup>d</sup> With respect to scarlet-fever, the names of the species are not (as is the case in many other cutaneous affections<sup>e</sup>) unworthy of being remembered. The distinctions of this disease are very proper; but we have only to remember that there is a mild form of the disease; another in which the throat is much affected; and another where there are typhoid symptoms. In this violent typhoid form of the disease, the efflorescence

<sup>d</sup> See Dr. Willan's “Description and Treatment of Cutaneous Diseases;” Order 3; Genus 2; Species 3; Plate 21.

<sup>e</sup> See Pages 367, 368, 375, and 378.

is dark and livid. It comes out even still later than in "*scarlatina anginosa*" (where the disease is attended by an inflammatory sore-throat); and it is of uncertain duration. It is continually going and returning; and there is less heat of the body. In "*scarlatina anginosa*," I said the heat might be 112 degrees; but here there is less heat; and the pulse, although perhaps very quick, is languid. There is great affection of the head;—great delirium or coma. In fact there is encephalitis;—inflammation within the head; and sometimes other inflammatory affections are present. The eyes are red, and the cheeks darkly flushed. There are sordes of the tongue and mouth; dark sloughs (the basis of which are livid) in the throat; and great fetor from the nose and mouth. There is an acrid discharge through the nostrils;—a discharge which irritates the skin upon which it flows. There is diarrhœa; and frequently there are petechiæ;—black specks on the surface of the body. Hæmorrhage occurs; and death often takes place in two or three weeks. Sometimes the patient sinks suddenly, within the first four days. Occasionally the disease does not show this malignant character at first; but goes on pretty mildly; and then, all at once, puts on these malignant symptoms. When the body is inspected, there are found to be various internal congestions, inflammations, and effusions; and inflammation of the surface (not of the *interior*) of the skin.

It is this frightful form of the disease which, when recovered from, leaves very severe complaints;—as ulceration within the ears, chronic diarrhœa, and such diseases of the skin as rupia and ecthyma. I do not know that this form of the disease is more frequently followed by anasarca than the others. So comparatively rare, however, is this species of the affection, that I have never yet had occasion to treat a patient with it. It is, perhaps, a singular thing, that I have yet lost only two patients with scarlet-fever. But it has solely arisen from this circumstance;—that they have always been *mild* cases which I have treated;—such cases as required cold washing, cold air, and occasionally the local application of leeches. I have heard other practitioners say, that they never lost a case of scarlet-fever.

We sometimes see that form of the disease which is called "*scarlatina maligna*," occurring generally throughout a neighbourhood;—at least generally during an epidemic. Sometimes we see one person in a neighbourhood affected with it; while other persons, or other children, are affected with other forms of the disease. Sometimes, even in the same house, we see all the three forms of the disease. It appears, therefore, that the cause of the disease's putting on this malignant character, is sometimes something general in the state of the season or place; and sometimes something altogether dependent upon the condition of the individual. It does not appear to be any thing peculiar in the contagion. We shall find, in the case of small-pox, that matter taken from a person labouring under a mild variety, will sometimes give to another person a malignant, confluent, violent form of the disease. So, in scarlet-fever, the *mild* form of the disease, is sometimes caught from a person labouring under a *malignant* form; and *vice versâ*; and although we see numerous cases of malignant scarlatina, during a particular epidemic,—and especially in a particular neighbourhood,—yet, at other times, we shall see the malignant form occur sporadically. It may occur only in one or two individuals in a neighbourhood; while the rest have the mild, or merely the inflammatory form; and we even sometimes see this peculiarity cease in one place, while another becomes filled with the inflammatory or mild form. I believe that the malignant form is more common in winter, than at any other period. The circumstances that give rise to it are not well known.

4. *Scarlatina Fancium*.—There is, however, another form of the disease, in which the *throat* is affected, and not the *surface*. Some, indeed, have denied this;—just as some have denied that measles are occasionally seen without catarrh. As, however, this disease affects both the surface and the throat; and as some have asserted that it frequently affects the surface, while there is little or no affection of the throat; so there is no reason whatever why the throat should sometimes not be sore, while the surface is scarcely or not at all affected;—while there is nothing

upon the surface worthy of the name of an eruption. Dr. Willan mentions,<sup>a</sup> that in epidemic scarlatina, there are always many cases where the throat only is affected; and that these cases will communicate all forms of the disease, just as if the skin were affected. This, I think, is not at all surprising. In that form in which the throat particularly suffers, if we were to look over the skin from head to foot, two or three successive days, we might perhaps discover an eruption; but it would be so little, that we should be almost justified in saying there was none; and I have seen several in a family affected with the sore-throat only; and that mildly. Those who formerly had scarlet-fever, and even those that are recovering from it, if they be exposed to the contagion again, will sometimes have a little soreness of the throat, and even patches on the skin.

*It may Occur more than Once.*—It is a disease that usually occurs but once during life; but I believe the exceptions to this rule are more frequent, than in the case of small-pox. Small-pox occurs twice, more frequently than measles; and I believe scarlet-fever occurs twice, more frequently than small-pox. But I am not certain; for some persons do not make a sufficiently accurate diagnosis, between such a rash as roseola and scarlet-fever. Still, however, it is by no means uncommon for persons that have had scarlet-fever, to have a sore-throat, if they be exposed to the infection of an individual labouring under this disease. It is by no means unusual for those who have about them children labouring under scarlet-fever, to have a sore-throat, characterized by intense redness; and that sore-throat is sometimes very severe. Occasionally, persons who have had scarlatina formerly, or are recovering from it, have not only sore-throat (if strongly exposed to the contagion), but even spots like flea-bites, sometimes of a dark colour. Dr. Willan says, that he never saw the disease occur more than once; although he had witnessed two thousand cases of it. When I was a pupil, it was denied that small-pox or measles ever occurred twice; but now that there are so many persons capable of making good observation, cases have been sufficiently multiplied to settle that point.

*Persons are not so liable to it.*—It differs, however, from measles and small-pox in this;—that persons generally are not so liable to it. Almost every body has the small-pox, unless they have had the cow-pock, and are thus prevented; but we find a great number of persons that never had scarlet-fever. It is common to find persons that never had the scarlet-fever, although they have been exposed to the contagion; but it is very uncommon to find persons that have not had the small-pox (or the cow-pock) and measles. I have been exposed to scarlet-fever often enough; but I never had it; though I have had small-pox, measles, and whooping-cough; and the rest of the diseases which people usually have.

*Causes.*—Scarlet-fever arises solely from contagion. I use the word “contagion” in its generic sense. The disease may be caught by being near a person labouring under it; and therefore it is infectious. It may be caught, too, by touching any thing that the individual has touched; and it may be caught from a second person. If an individual visits a person labouring under the disease, and then visits another, the second person visited may catch it from him. It may be communicated too, it is said, by the exfoliated portions of cuticle. It may be conceived, that these are so abundantly impregnated with the perspiration, as to communicate the disease; but I do not know, from observation, whether this is the case. It occurs more frequently in children than in adults; but extreme infancy is least liable to it;—just as it is least liable to measles. Being of an infectious nature, the disease is often epidemic; but it is more prevalent at the equinoxes, than at any other period of the year.

*Diagnosis.*—[The only diseases with which scarlatina can be confounded, are measles and roseola. From measles it may be distinguished by the precursory symptoms; by the time intervening between the first accession of fever, and the appearance of the rash; by the character of the eruption; and by the sequelæ. Measles commences with coryza, sneezing, suffusion of the eyes, cough, slight

<sup>a</sup> See Note (a) to Page 389.

dyspnœa, and other catarrhal symptoms; while, in scarlatina, the first sensation of uneasiness is referred to the throat. The eruption in measles shows itself on the fourth day of the fever; but in scarlatina it may usually be distinguished on the second. In measles, the rash is disposed in irregular portions, of a crescentic form, and is slightly elevated,—so as to be sensible to the touch; in scarlatina, the eruption assumes the appearance of broad patches, of an intermediate shape. The rash has a different tint in the two diseases; it is of a vivid red in scarlatina, but of a darker or raspberry-hue in measles. In scarlatina, the fever does not abate upon the appearance of the eruption to the same extent as in measles, the former is frequently succeeded by anasarca, inflammation of serous membranes, depositions in the joints, &c. The sequelæ of measles are principally affections of the respiratory organs; as bronchitis, pneumonia, croup, &c.

Roseola is distinguished from scarlatina by the partial and regularly defined rash, by the absence of angina, by the mildness of the febrile disorder, and by the short duration of the complaint. Deep rose-coloured patches, exactly like roseola, sometimes appear intermixed with the rash of scarlatina.

*Prognosis.*—The only danger to be apprehended in “scarlatina simplex,” is the occurrence of some internal local inflammation, or the supervention of anasarca, when the desquamation of the cuticle is completed. It must also be borne in mind, when scarlatina prevails epidemically, that a mild case sometimes suddenly assumes a malignant type. The prognosis in “scarlatina anginosa” is influenced, chiefly, by the extent and severity of the local inflammation;—bearing in mind, however, that there is a natural tendency in angina to terminate in resolution. A bright florid appearance of the inflamed mucous membrane, is a more favourable symptom than when it presents a dark livid aspect. But if there is excessive tumefaction of the throat and surrounding parts, and especially if the inflammation has extended to the air-tubes, the disease is to be considered dangerous, and will probably terminate fatally. In some cases of this kind, œdema of the glottis<sup>a</sup> supervenes, and rapidly destroys the patient. The prognosis is also unfavourable if the delirium commences, as it frequently does in children and young persons, a few hours after the seizure: in these cases a fatal result often ensues in the course of two, three, or four days. Our prognosis may often be formed from the character of the eruption. A bright red efflorescence is more favourable than a pale rash, or a dusky red, or one of a raspberry tint. When the eruption is partial and evanescent, or when its retrocession takes place suddenly at an early stage without reappearing, there is much cause for apprehension. Complete desquamation of the cuticle is a favourable sign. “Scarlatina maligna” being always attended with great danger, a guarded prognosis should be given.

Of the circumstances indicating a minor degree of danger, the following are the more important. It is generally supposed, that children withstand the virulence of this disease better than those of more advanced age. The absence of visceral inflammation, or of structural disease of any important organ, will also lessen the danger. A plentiful and florid eruption, a bright red colour of the fauces, and a disposition of the exudations on the throat to separate, universal desquamation of the cuticle, the pulse falling in frequency and rising in power, the breathing becoming gentle and free, the countenance resuming its natural expression, and gentle perspiration, are indications of a favourable result.

Among the unfavourable signs are the existence of inflammation in an important organ, for the subduing of which active remedies cannot be employed; a dark or livid appearance of the eruption, more especially when intermixed with petechiæ; the sudden disappearance of the efflorescence; a small frequent pulse, with great prostration of strength; hurried respiration, not depending on active inflammation of the lungs; acrid discharges from the nose and ears; the admixture of blood in the urine or stools; involuntary evacuations; subsultus tendinum; hiccup; mut-

<sup>a</sup> From γλῶττα, the tongue.

tering delirium and coma; the appearance of gangrene of those parts subjected to pressure, or in the extremities.

In conclusion, it may be remarked, that it is often a fatal disease when it attacks pregnant or puerperal women; and that it is generally of a milder character in the spring and summer, than in the autumn or winter months.<sup>a]</sup>

*Treatment.*—The treatment of this disease is, for the most part, very simple. If we take care to do the patient no harm, he in general will do very well. In this disease, cleanliness and fresh air should be particularly attended to. If the season will allow it, the windows and doors should be opened; and only the slightest covering placed upon the patient. Cold water (or something nearly as simple as water) is the most eligible drink. No food beyond this, except it be milk-and-water, should be allowed. The bowels, of course, should be kept open. It is said that an emetic, given early, alleviates the disease. Some are of a different opinion; but many contend that, at the beginning of the disease, it is very good.

*Cold Affusion.*—The disease certainly has been cut short, by taking a patient out of bed, and pouring cold water upon him. The heat of the body is so great, in this disease, that no danger is to be apprehended from cold affusion. It is true, there are cases in which the patient is more or less chilly; but if, in this affection, the general rules which I laid down in the case of common fever be followed, there is no danger whatever, but the greatest advantage, in taking the patient out of bed (however hot he may be) and pouring cold water upon him. Those rules are,—that the temperature is steadily above 98 degrees; that there are no profuse general sweats; that there is no chilliness; and no inflammation of the chest or abdomen. I presume this would be done oftener than it is, were it not for its appearing a violent measure to take a person in fever out of bed, put him into a washing-tub, and souse him well with cold water. But, at any rate, no friends will object to washing a patient with cold water. It is a great comfort to the individual; and, as long as it is comfortable, it should be had recourse to. Sponging the hands, arms, face, and trunk, with cold water, is grateful to the patient; and is an excellent practice in the disease.

*Bleeding.*—If the inflammatory symptoms run high, it will be necessary to bleed in the arm. In general, it is only requisite to give the patient fresh air; to give him little better than water to drink, and nothing to eat; to keep him clean; let him have but few clothes upon him; and to keep his bowels open. But if the symptoms should be violent,—that is to say, if any local inflammation come on in the head, chest, or abdomen,—it may be necessary to take blood from the arm. We are not to neglect local inflammation, because the affection under which the patient labours is scarlet-fever. For the most part, this inflammation may be subdued by local bleeding; and it is best to remove it by that means, if we can; because it produces less debility, than if we take blood from the arm with a sudden shock. It is to be remembered, however, that the case may be so severe, as to render general bleeding imperative.

*Relieve the State of the Throat.*—The chief parts that suffer, in this disease, are the throat and head. The throat suffers, because it is one of the seats of the disease. The application of leeches around it, is exceedingly useful;—far better than a blister; as I shall mention when I come to speak of common sore-throat. In that affection, blisters are frequently very severe; but leeches afford immediate relief; and plenty of leeches about the throat, or about the head, are often valuable in scarlet-fever. The tongue may be particularly foul in this disease; and that might give rise to the belief that there was great disturbance of the digestive organs; and therefore that emetics, calomel, and remedies of that description, were particularly necessary. But this, I think, is a wrong inference; for the tongue is one of the seats of the disease. It is not foul because there is intense feverishness of the system; but foul because it is in a state of inflammation. The papillæ are exceedingly red; the tip is red; and the secretion on the back of the tongue is diseased,

<sup>a</sup> "Library of Medicine;" Volume 1; Pages 343 and 344.

both in quantity and quality. We may have, in fact, (besides the redness of the papillæ,) just such a tongue, with respect to the dorsum, that we have when a person is fully under the influence of mercury;—a tongue covered with a thick, yellow mucus. The tongue itself is swollen.

This state of the mouth is much alleviated, by allowing the patient cold drinks; or, if it be agreeable, he may have them iced; for the heat of the throat and mouth is very great. We continually see sloughs formed upon the throat. I mentioned<sup>a</sup> that it is not every thing which *looks* like a slough, that *is* one; because the disease produces the effusion of shreds of lymph; and they lie there as though it was a little ulcer; but occasionally we have dark and ash-coloured specks, which cannot easily be removed; and which are neither more nor less than so many sloughs. In the malignant form we have very considerable sloughs. These—whether they be mere shreds of lymph, or sloughs—are always best treated by gargles of the chloride of soda or lime. The more intense the gangrenous tendency, the stronger must be the gargle. In ordinary cases of scarlatina, a gargle composed of two ounces of the common solution, to half a pint of water, is found strong enough. It will produce a pricking sensation, and is even sometimes too strong; but in other cases, where the sloughs are very considerable, we may employ it much stronger than this. In the merest specks of the throat, this is one of the best applications that can be employed. However, there is frequently a difficulty in the application of gargles; and then it is better to use a syringe, and squirt the gargle at the throat; if any of it be swallowed, it is a good internal medicine, and will do no harm. I know no gargle to be compared with a diluted solution of chloride of soda or lime; both in cases of scarlet-fever, and in cases of thrush.

*Stimuli.*—If the disease show a very considerable gangrenous tendency in the throat, and the pulse be very soft and feeble, we have only to treat it, generally, as we would treat any case of typhus-fever. Among the internal stimulating medicines, which it is found necessary to give in the latter stages, sesquicarbonate of ammonia is the best; with the exception, perhaps, of wine; which generally answers better than any thing else. Patients will sometimes take a great quantity of wine, in this disease. Dr. Withering, who wrote on this disease, says that, in an epidemic which prevailed among a number of children (about twelve years before he wrote), each must have taken a bottle of the best port-wine in twenty-four hours, for several successive days. A quantity of wine is borne, on these occasions, which would intoxicate and destroy at other periods. The treatment is the same as for typhus-fever, where there is great debility, or a tendency to putrescence, or mortification.

*Ammonia.*—Some persons think that ammonia has a peculiar power in this disease; and they say they have given it in every case of every description, whether inflammatory or not; and that they never lost a case in their lives. I presume that very few of the cases which these gentlemen treated, were of a malignant character; and that if they had merely given all the children a piece of *sugar* once in the twenty-four hours, still the greater number would have done almost as well. This is a disease which, for the most part, terminates favourably, if the practitioner does no harm; and a little ammonia can do none; but, by rational treatment, it runs its course more mildly; and saves the patient a great deal of suffering.

*Recession of the Eruption.*—If the eruption recede, the best treatment is to put the patient into a hot-bath, several times a day: to rub the body with stimulants; and to give stimuli internally. But it is necessary here, as in other similar cases, to observe whether an internal inflammation has come on. It may be that which prevents the patches from coming out; and, in such a case, we must be careful not to give internal stimuli; but rather apply leeches, to remove the internal congestion and inflammation. We may stimulate the surface at the same time; but the great point is to alleviate the *internal* affection, which prevents the *external*.

*Prophylactics.*—As this is a disease which children do not *necessarily* take, as

<sup>a</sup> See Page 390.

they do measles and small-pox, it is but fair to endeavour to prevent them from catching it; and, besides free ventilation and cleanliness in the house, the use of the chlorides may be proper, with a view of destroying the contagion. I do not know whether they *do* destroy contagion; because I have recourse, in addition, to fresh air, plenty of water, and cleanliness; and, as I feel it my duty to use the chlorides at the same time, it is impossible to say what is done by the one, and what by the other. I have no means, therefore, of drawing a conclusion. But it would be well to throw the dirty linen, taken off the patient, into water in which the chlorides have been introduced; to put the chlorides into various utensils which are used; and to sprinkle them about the room. In this way, we may possibly prevent other persons in the house from catching the disease.

*Belladonna*.—A German physician, however, recommends a medicine for the purpose of preventing the disease, which appears to me of a very fanciful character. Dr. Hahnemann, of Leipsic, says that belladonna will prevent the disease. He says, that if we take two grains of the extract of belladonna,<sup>a</sup> and dissolve them in one ounce of cinnamon-water, or pure water (which is much the same thing), and give two minims of this solution to a child a year old (or another minim or two according to the age of the child), we may prevent the disease. I never thought it worth while to try it; because I hardly think the observations which are published conclusive. I know that foreign physicians have since published accounts of the disease being so prevented; but it ought to be from hundreds of observations, that any one says the disease has been prevented; because it is an affection that will not attack every one in a house; and, every now and then, when the disease has been spreading for some weeks, all at once it will disappear, and no other persons have it. Inferences, therefore, ought not to be drawn without very numerous facts, —numerous coincidences, well ascertained.

*Treatment of the Anasarca*.—With regard to the anasarca which follows this disease, I have no doubt that it frequently arises from cold; for it either begins in the face, or the face is affected as soon as any other part. It may be attributable to exposure to cold when the disease is over, or declining; because it is an affection that does not take place *during* the disease, but *subsequently* to it. Rayer condemns the application of cold in the disease; because it is likely to produce anasarca. Now I have generally used cold ablution (not *affusion*) in this disease; and never, when I treated the case myself, has anasarca occurred. I do not believe that, if a low temperature be applied properly (that is to say, when the heat of the body is too great), there is any danger of the patient catching cold; but if it be used when the patient is not hotter than he should be, or after the disease has declined, then I have no doubt that it would lead to anasarca. However, this anasarca appears to be inflammatory; and for this reason it resembles the anasarca which is the effect of exposure to cold;—especially cold united with wet. It begins in the face; or it particularly affects the face; or it is seen in the face as soon as anywhere; and, in the next place, the urine is often albuminous. It will not merely contain *albumen*, however, but sometimes *blood*. In most cases of anasarca which I have seen, (and perhaps I have seen them only because they were intense,) there has been more or less internal inflammation, in the head, chest, or abdomen;—just as in acute anasarca from cold. In almost every case, it was in the chest; generally pneumonia or pleuritis.

The treatment of this anasarca is best conducted by antiphlogistic means;—by purging the patient well (which is an antiphlogistic remedy); and some say by giving digitalis;<sup>b</sup> but I know that it recedes best by purging; and by attending to any internal inflammation that may exist. It would be in vain to purge, in severe inflammation of the chest, unless we made use of leeches at the same time; and the same remark applies to the head. It is important, in all these cases of anasarca supervening on scarlatina, to examine whether there be inflammation; for if we

<sup>a</sup> From "*bella donna*," (Italian), *fine lady*;—so named from its employment by the Italian ladies, as a cosmetic.

<sup>b</sup> From "*digitus*," a *finger*;—from the shape of its flower.

neglect that, the anasarca will generally be tiresome, but if we treat that, it will go away. Occasionally the anasarca goes away of itself; but we may always expedite it by purging, or by briskly applying antiphlogistic measures, directed towards some internal part. I do not know whether it is mentioned by any author; but, besides phrenitis or arachnitis, rheumatism is not an uncommon sequela of scarlatina.

## SECTION VI.—ERYSIPELAS.

The next disease which I shall describe, is one that I hardly know where to place;—I mean *erysipelas*.<sup>a</sup> Rayer places it with the rashes, because there is a continuous redness of the skin; but Willan places it among those which have a large collection of water (“*bullæ*.”)<sup>b</sup> The truth is, this disease may exist without the formation of any secretion,—without any collection of water, or even watery vesicles, yet I think that, in a great number of cases, it does produce an elevation of the cuticle (of smaller or larger size) containing water. Upon the whole, it may be right to place it with the rashes;—as the redness is diffused, and always exists, whereas vesicles, or bullæ, do not. But it is a matter of no very great importance.

*Essential Characters*.—Erysipelas is a very intense affection; of the same description as roseola and erythema. What roseola and erythema are mildly, erysipelas is severely. If there be a diffused redness of the skin, with heat and more or less smarting, without disturbance of the constitution, and without any swelling of any consequence, we may call it “erythema;” if the symptoms be equally mild, and the rash is rose-coloured, we may call it “roseola;” but if the part be much swollen, the inflammation very intense, the pain and heat very great, and the constitution be disturbed;—then we call it “erysipelas.” It differs from erythema in this:—that while the inflammation of erythema may be *chronic*, (as in “erythema nodosum,” or “erythema tuberculatum,”) erysipelas is always an *acute* febrile disease;—attended with heat, swelling, pain (which erythema and roseola may not be), redness of some part of the skin in patches; and often united with vesication. The swelling is irregularly circumscribed; and is generally soft. Generally the redness disappears on pressure, and instantly returns when the pressure is removed; as in erythema and roseola.

*Progress of the Disease*.—Very often, before this inflammation comes out, there is a previous excitement of the constitution; as is the case in measles and scarlet-fever. Before tenderness of the skin is felt, the patient may be feverish; or he may have headache, nausea, vomiting, drowsiness, vertigo, or tenderness of the epigastrium; or he may have rigors. After these symptoms (more or fewer of them) have existed in greater or less intensity, for two or three days, some part of the skin will feel sore; and, on being looked at, it will be found a little swelled, and a little red and hot. All this increases. The skin becomes more swelled; very red and very hot; the patient experiences pricking or smarting pains; and the general excitement and feverishness are increased. Occasionally the local symptoms appear first;—the feverishness taking place exactly in the same degree that they do; but sometimes we have the feverishness first, and then the redness appears. Very frequently, after a little time, minute vesicles are seen here and there, in the inflamed part. Frequently there are no vesicles at all; and when vesicles do appear, they frequently occur only in some particular parts of the red patches. Sometimes they are not very large;—they are really vesicles; but sometimes they are as large as walnuts; and are then called “bullæ” in Latin, and “blebs” in English. These contain, at first, a clear fluid; but sometimes, after a day or so, it becomes turbid; and is more or less yellow. These burst, and the fluid oozes out; so that a yellow

<sup>a</sup> From *εἰς*, *to draw*; and *πλάσις*, *near or adjoining*;—from its tendency to affect the neighbouring parts. Its common designation is—“St. Anthony’s fire.”

<sup>b</sup> See his “Description and Treatment of Cutaneous Diseases,” Order 4; Genus 1.

crust forms;—a crust which is made of this secretion dried, and the exfoliated cuticle. If the disease decline without forming any of these vesicles, or bullæ, the cuticle is sure to come off, and we have a scurf; but if there be vesicles, or bullæ, then we have crusts. Sometimes the surface under the elevated cuticle, after the bursting of the bladder, secretes pus;—more or less suppuration will take place; and sometimes the secretion, be it pus or mere lymph, is very acrimonious; so that it produces great irritation of those parts over which it flows.

*It has a tendency to Spread.*—This is a disease which has a great tendency to spread. It will sometimes spread over half the body. I have seen it spread from the occiput down to the toes. As it spreads, sometimes the part first affected recovers; at other times it does not;—so that we then have one immense sheet of red colour. It is sometimes very curious to see, as it spreads along, how the parts first affected become well.

*Metastasis.*—Now and then it will suddenly cease, and some internal part suffer. This change of situation is called “metastasis;” and if it only disappears in *one* part of the surface, to reappear in *another*, the French call the circumstance “delitescence;” but if an *internal* part be affected, it deserves the name of “metastasis.”

*Varieties.*—When it extends slowly from one part to another (whether the part affected recovers or not), it is called “erysipelas *erraticum*;”—wandering about. Sometimes there is very great swelling, and effusion of serum into the cellular membrane; and it is then called “erysipelas *œdematodes*;”—being œdematous. Now and then, the irritation of the cellular membrane under the skin, is much more severe than to secrete mere serum. It is so severe as to secrete pus; and then it is called “erysipelas *phlegmonodes*;”—it being the character of phlegmon to secrete pus. When this occurs,—when the cellular membrane underneath the skin becomes affected, as well as the skin itself, to a great degree,—there is extreme pain, extreme tension, extreme hardness. The limb feels as though it would burst; the patient is skin-bound; and the general symptoms, throughout the body, are excessively severe. Suppuration sometimes occurs only here and there; but sometimes it is very extensive. It is by no means uncommon, in partial phlegmonous erysipelas of the face, to see the affection suppurate in particular spots; as, for instance, at the orbit. The cellular membrane under the eyelids, is disposed to run into suppuration; when there is no suppuration in any other part of the face. But, besides this local “erysipelas *phlegmonodes*,” a whole extremity will sometimes fall into this particular state.

*Erysipelas Gangrænosum.*—The disease is very much disposed, in many cases, to produce mortification. Parts of the skin will often slough; the vesicles will become dark; and the fluid which is within them become bloody. But, besides that, the disease will frequently produce sloughing deeper in; and death will take place, to all appearance, from the gangrene. When this is the case, it is called “erysipelas *gangrænosum*.” Infants are very liable to this gangrenous erysipelas. New-born infants will frequently have it about the umbilicus and the genitals. I have seen this occur without any vesication. Round the umbilicus or the pudendum, in young children and infants, the parts will become very red, hot, and hard; the red will become dingy; and then gangrene take place, and the parts become perfectly black. In adults, this occurs very frequently in the extremities; but in the case of children, it is about the genitals and the umbilicus that it usually takes place.

We see, therefore, that this disease, (like continued fever, or any common inflammation, or like scarlatina,) runs from mere active inflammation with strength, on the one hand, down to the most perfect prostration of strength, and the most violent tendency to mortification, on the other. It is pretty evident, therefore, that no one mode of treatment can be adopted.

*Not confined to the Surface.*—Erysipelas is by no means confined to the surface of the body. We continually see the throat affected. If the inner part of the throat and mouth are the seat of the disease, the throat and tongue are red; the

patient complains of the mouth being exceedingly hot; perhaps there is a short cough, and difficulty of swallowing. In fact, there is a sore-throat. Very frequently, too, it will run down the membrane lining the tubes; so that there is a very severe cough, and a difficulty of breathing. We have more or less bronchitis; and sometimes there is really *severe* bronchitis; but for the most part, it is only a *superficial* sort of inflammation;—erysipelas of the mucous membrane; and will go away without the adoption of any strong measures.

*Complications.*—Very frequently, besides the sympathetic effect occurring at the beginning of the disease, there is great tenderness of the epigastrium;—the patient complaining of intense heat there; and sometimes the same is felt all over the abdomen, as if the inner surface of the intestines were in a state of erysipelas; and then diarrhœa occurs. I have seen the disease spread down the air-passages, and then down the alimentary canal. But, besides this spreading from the skin through the ramifications of the trachea and bronchia, and through the pharynx<sup>a</sup> and œsophagus<sup>b</sup> to the stomach, and down to the intestines, we continually see the membranes of the brain affected, when the head and scalp are the seat of the disease. When the disease affects the inside of the head, (which it is much disposed to do, after it has attacked the face, neck, and scalp,) the danger arises from inflammation of the membranes of the brain; so that, as the disease advances, we have extreme drowsiness. The patient complains of internal pain of the head; delirium comes on; and, at last, there is more or less of an apoplectic state.

When the patient dies with symptoms of inflammation within the head (such as drowsiness, delirium, &c.), I have always found, within the skull, certainly not inflammation, but the *effects* of inflammation;—effusion. I have always seen an effusion of serum upon the brain, or in the ventricles, or in both situations; and sometimes great turgescence of the vessels.

*Erysipelas of the Face.*—When the face is affected, the eyes are closed and the features lost;—from the general swelling and effusion into the cellular membrane. The person becomes, in his appearance, as ill-looking a fellow as can be conceived. His nose is bottled, and is buried in his cheeks;—in fact, he looks as if he had been drinking hard, and had had a good drubbing. The features are set, the eyes closed; and there he lies;—not to be recognized by any one. I know this by my own case;—having myself laboured under the disease. My friends brought a looking-glass; and, on raising the upper eyelid, I took a peep at myself; but the sight was so abominable, that I begged the glass might be removed.

*Causes.*—The common causes of the disease, are vicissitudes of temperature, and exposure to cold;—especially when the person is heated. But it very commonly arises from some *local* cause;—mechanical injury, or any thing that irritates. It is much predisposed to by certain situations. There are certain situations, in which erysipelas is very common. There are hospitals, it is said, where erysipelas is more common than in others. It certainly appears to be dependent, in some measure, upon the season. At particular periods, in several hospitals in the same town, where there had been no erysipelas, the affection will, all at once, become very common. These circumstances may be so strong that, without any local irritation, patients will be seized with erysipelas; and the slightest local injury will sometimes cause it. Erysipelas, in these particular seasons, or in these neighbourhoods, may be followed by the most violent inflammation. Persons of bad constitution are also very liable to it. Those who have been in the habit of drinking spirits, or have ruined their constitution in any other way, are very likely, from the least injury (even from leech-bites), to fall into this disease.

*Is Erysipelas Contagious?*—It is said, by some, that erysipelas is occasionally contagious. Dr. Wells (as I mentioned formerly<sup>c</sup>), published a number of cases to prove it contagious.<sup>d</sup> It does appear that, in the cases he mentioned, it

<sup>a</sup> From φέρω, to carry; because it conveys the food into the gullet.

<sup>b</sup> From αὖω, to carry; and φάγω, to eat; because it conveys the food into the stomach.

<sup>c</sup> See Page 135.

<sup>d</sup> In the "Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge," Volume 2; Page 213.

was contagious. The instances were numerous; and they were cases of persons who went to visit others who had erysipelas; and then went back, and gave it to others in their own houses. I cannot exactly say that I have seen it contagious. In hospitals, I (in common, I suppose, with every other practitioner in similar circumstances) have seen patient after patient, in a ward, become affected; but whether it arose from local circumstances, or from emanations spreading from one individual to another, I cannot tell. I recollect once having had it, five days after stooping down over a patient, who had the disease in so violent a form that he died of it. I was looking into the state of his skin; and his breath came into my face. I turned away with a feeling of disgust; and said,—“I hope I have not caught it;” but, five days afterwards, having forgotten the circumstance, I was seized with erysipelas. I felt chilly, and my head was sore; and I had the disease violently. This was in the winter, when a person is liable to catch cold; and therefore I am not sure that I caught the disease from contagion; though, so far as I am aware, I never take cold. I have seen instances where the affection might have been contagious; but I am not sure that such was the case.

*Treatment.*—The treatment of the disease must be totally different in different cases. In the country, and in young, strong, healthy subjects even in town, there can be no doubt of the propriety of taking away blood from the arm. I have often bled patients, and was repeatedly bled myself; and with the best effects. On the other hand, if a patient have a shattered constitution, either in consequence of being half-starved, or of intemperance, or any thing else, then we must employ bleeding with great caution. But still, in the greater number of cases, antiphlogistics are the proper remedies; though perhaps they should not be carried to a great extent. Purging, and the other parts of the antiphlogistic plan, are necessary.

*Cold Applications.*—I have always found cold useful; and I never saw the disease recede in consequence of it, or internal disease produced by it. I employed it in my own case. The application of cold water, either directly, or by means of rags, is very uncomfortable to the patient, after a time; and as soon as this effect is produced, it is but common sense to leave off the application of cold. If fresh air can be obtained, it should be had recourse to in this, as in most other diseases.

*Local Bleeding.*—Frequently local bleeding will answer every purpose; but I should never shrink from general bleeding, if it appeared desirable. There is nothing to fear from it. With regard to local bleeding, we may employ it by means of leeches around the part; or we may put them on the part itself. There is no harm in adopting the latter plan. I was not aware of this at one period; but I have tried it; and now I know it by experience. Some think it is more eligible to take away the blood by means of needles, or the point of the lancet; because then there is not that irritation, which is occasioned by the bite of a leech. I have never seen harm result from leech-bites, when they were applied around the inflamed part, or to the part itself; but it is said there never is any danger, if we withdraw the blood by means of acupuncture. There is a vast collection of blood in the erysipelatous part; and, by puncture, we may frequently unload it to a great amount.

*Nitrate of Silver.*—We may put a stop to the progress of the disease, by the application of the nitrate of silver. I have done so very frequently. If we rub the nitrate of silver on the healthy part around the disease, or make a strong solution and apply it all round with a brush, we may generally prevent its farther progress. Some persons recommend blisters; but the nitrate of silver answers much better. I have stopped the disease, over and over again, by this means; and I should feel it right to have recourse to it, in every severe case. We are indebted for a knowledge of its use to Mr. Higginbottom, of Nottingham; who has written a work to show the good effects of this remedy, not only around the part, in this way, but applied to the inflamed part itself.<sup>a</sup> It is necessary, however, that the application should be continuous; for if we allow a small place at which the disease

<sup>a</sup> “An Essay on the Use of the Nitrate of Silver in the cure of Inflammation, Wounds, and Ulcers. By J. Higginbottom.” Second Edition.

can creep out, it will be sure to do so. I have seen cases where a portion was left unguarded; and I have seen the affection creep through there, and spread along the part. It is very important to stop the progress of the disease, if it be near the head; because if it should spread over the head, or even half over it, it is ten chances to one that we have delirium, and inflammation of the membranes of the brain; and the patient will die in an apoplectic state.

*Incisions.*—If there be much tension in the part, there is no impropriety in doing something more than merely emptying it by leeches. Indeed, it is very important to make an incision in it, by means of a lancet; and the tension will then sometimes cease immediately. It is in “erysipelas *phlegmonodes*” that this is particularly required. Generally, if we take away blood, purge, starve, and apply cold, the disease will give way; but if there be this extreme tension, and we make an incision, the wound immediately stretches;—just as it would if we had made a cut in a shoulder of mutton. The practice is now, I suppose, well established. Some surgeons make the incision a foot long; but others make half a dozen incisions, each an inch in length;—some doing it all at once; and others, as Mr. Lawrence once waggishly said, “by instalments.” That, however, is a matter of surgical choice. But there can be no question, I think, as to the advantage of making incisions, for the purpose of letting out blood or pus; or (before pus is formed) merely to take off the tension, by allowing the blood to ooze from the part.

*Treatment of Mortification.*—In case mortification is threatened or occurs, we have to consider whether it depends upon the violence of the inflammation. If the inflammation be violent, we must not, because there is mortification, give wine, bark, and opium; but must strive to subdue the inflammation by antiphlogistic means. Again: if we see or fear a sinking of the constitution, even if there be no mortification, then wine, porter, opium, bark, and good food must be given;—just as would be the practice in any common case of inflammation.

In doubtful cases, when we hesitate whether to bleed and put the antiphlogistic plan into force, or to stimulate and support, the best plan is to apply cold effectually; to unload the part by leeches or punctures; and to give beef-tea, milk, and quina. I have never seen quina do harm, even in active tonic erysipelas; and, in doubtful cases, I believe it always a safe and eligible medicine. In other cases of inflammation, I have thought that the time was arrived for this species of treatment, when it was not; and have been obliged to desist; but, in erysipelas, such a circumstance very seldom occurs. Dr. Heberden gave it as his opinion, that bark would not do harm in inflammation; and in a great many cases that opinion is true; but as to quina, I have given it over and over again in inflammation, for some other reason, (for example, in ague,) and have not seen the inflammation increased by it; but in these cases I have always treated the inflammation, at the same time, by proper measures. Hence, in erysipelas, if we feel disposed, we may always give quina, unless there should be vomiting; and even then, where the vomiting was not inflammatory, I have given it; and it has put a stop to the vomiting. Therefore, though this is a disease that is to be treated by decided antiphlogistic measures, yet it permits the exhibition of wine, bark, and porter; and though we adopt antiphlogistic measures, yet it does not bear those vacuations which other inflammatory diseases do. It sooner requires supporting measures, and a larger number of cases require support, than perhaps in any other inflammation.

*Bark.*—Some old practitioners imagine (from having learned it in their youth) that bark is a specific for this disease; and in every case of erysipelas they give, or (as they call it) “throw in,” the bark. It was at St. Thomas’s Hospital that this practice was first established. Dr. Fordyce gave bark in erysipelas with very great success; and his colleagues and successors, down to within a very few years, all adopted the same practice, and extolled it highly. But I never fell into the practice of giving bark universally, without regard to the state of the patient. Very often there is tenderness of the epigastrium; very often there is vomiting; very often there is a robust constitution and a strong pulse;—in short, a decidedly inflammatory state; and I could not, in my conscience, think of treating the case with

bark. No doubt bark might be given, in many inflammatory diseases, without doing any harm, except so far as it prevented us from doing good; but there are many cases where antiphlogistic measures are decidedly required; and I could not bring myself to omit them. There are many gentlemen now in practice, who were educated under Dr. Fordyce—the principal medical lecturer in London at that time; and they regularly give bark in this disease. I have no doubt that a number of their patients get well, because many cases are assisted by the bark; and many cases will get well of themselves, if we do not adopt any measures which do serious harm.

There is certainly a great peculiarity in erysipelas. Many cases do well, with little or no treatment; without those evacuations that other inflammatory diseases require. I have seen cases neglected, which, had they been pleuritis or enteritis, would have proved fatal without vigorous antiphlogistic treatment; but which, notwithstanding they were neglected, did exceedingly well. Erysipelas is considered a specific inflammation; not contagious, like small-pox; not limited in its occurrence to once during life; but still altogether of a peculiar nature. It will bear stimulants, and bark, and nourishment, in a way that other inflammations will not; nor will these things do the same degree of harm that would ensue from their exhibition in other inflammatory complaints. We may omit antiphlogistic measures, to an extent that we dare not in other cases; and it will require on the whole (however violent the inflammation) much more moderate evacuations, and will bear great evacuations less easily than other inflammations.

*Local Applications.*—Respecting local applications, I have found cold answer better than heat. Some practitioners sprinkle starch and other powders over the skin; and I do not know that it does any harm; provided the powder be of the lightest possible description, so as not to lie heavy on the part. If there be vesication, it certainly is a good plan to sprinkle a little powder, for the purpose of absorbing any discharge that may have oozed out.<sup>a</sup> The oxide of zinc, or calamine-powder, either the one or the other, is as good an application as can be employed; but this should not prevent the application of cold water; which may still be done by means of cloths.

---

## CHAPTER III.

### SQUAMÆ.

I now proceed to consider those inflammations which, although they are attended by no secretion under the skin, still cause such a disease of the cuticle, that a scale is produced. After those inflammations of which I have already spoken,—lichen,<sup>b</sup> strophulus,<sup>c</sup> measles,<sup>d</sup> &c.,—there is, for the most part, a degree of scurfy exfoliation. The cuticle is separated, more or less; either in fine grains (so as to form a scurf), or in large portions. But the diseases we are about to consider, produce something more than a separation of the cuticle. The latter becomes somewhat diseased; and lies in plates upon the inflamed spot. That is the only difference. These thickened portions of cuticle are called “scales.” Dr. Willan’s definition of a “scale” is,—“a lamina of morbid cuticle; hard, thickened, whitish, and

<sup>a</sup> The late Dr. Fletcher, of Edinburgh, used to relate that, in an attack of erysipelas under which he suffered, he derived the greatest comfort from the application of blotting paper, to absorb the discharge.

<sup>b</sup> See Page 369.

<sup>c</sup> See Page 367.

<sup>d</sup> See Page 381.

opaque.”<sup>a</sup> A “*scurf*” is only a little exfoliation of cuticle;<sup>b</sup>—the cutis not becoming diseased; but if the cuticle be not merely separated, but become “hard, thickened, whitish, and opaque,” then it is called “a *scale*.” Still, however, there is no ulceration. There is neither pus, nor serum, nor any other fluid effused under the cuticle; but the cuticle is separated; and not only separated, as in common inflammation, but thickened and diseased. In this order of diseases, there are three genera;<sup>c</sup> and they are of common occurrence. None of them are contagious. They may occur twenty times during life; and are all disposed to become chronic.

## SECTION I.—PITYRIASIS.

*Pityriasis Capitis*.—I shall describe pityriasis first; because the scales are exceedingly thin, and the affection altogether very superficial. When it occurs in the head of children, it is called “*pityriasis capitis*,”—“dandriff of the head.” When a child’s head has this disease, a fine powder falls off in all directions;—in fact, it is called “*pityriasis*” from its resemblance to *bran* (πικτυρον). It is a very common disease of children. Now and then the inflammation under these scales is considerable; and then it is called “*pityriasis rubra*.” It is only worth while to remember that, according to the degree of inflammation of the skin underneath the scale, the part is either rather pale or pretty red.<sup>d</sup>

*Treatment*.—This is a disease which lasts only for a time in children. For the most part, it gets well; and, I dare say, sometimes spontaneously. It is best treated as inflammation;—having the parts pretty well moistened, twice a day; keeping them exceedingly clean; and depriving the child of stimulants. Small doses of Hydrargyrum cum Cretâ, I believe, are the best internal means that can be used; the best, at least, that I have found. It is said, by Bateman, to be removed by antimonials, with the decoction of woods;<sup>e</sup> but I have no faith in these; and I know, that the plan I have stated, answers better than any thing else. You may keep the parts soft by Unguentum Zinci, which is one of the best ointments: but it is well to know that, in diseases of the skin, ointment (however mild) may produce irritation. It is well to remember this; because we might imagine, that it was only something *stimulating* in the ointment that was injurious; and that a *milder* ointment would answer better; whereas it is the ointment *itself* which produces the mischief. I have seen the disease kept up entirely by the application of grease; and when the patients have exchanged it for calamine-powder, and kept the parts moist by rags laid on them, they have improved almost immediately.

*Pityriasis Versicolor*.—Pityriasis is said to occur frequently in another form; but I am not sure that it is really the same disease. It occurs in young women, particularly about the breasts; and sometimes there are yellow patches of it on the neck. This disease is called by Willan<sup>f</sup> “*pityriasis versicolor*,”—“*variegated pityriasis*,” but Rayer does not place it under “*pityriasis*.” Now and then there is a little redness, a little heat, and a little scurf. I do not believe that this variegated pityriasis is under the influence of internal medicine. At least, I have tried a great many prescriptions without any effect. We may destroy it by the local application of acids. This remedy is painful; but we may apply it to a portion of

<sup>a</sup> “Description and Treatment of Cutaneous Diseases. By Robert Willan, M. D.” Definition 2. (Page 12 of the first Edition.)

<sup>b</sup> “Scurf” (*furfura*); small exfoliations of the cuticle, which take place after some eruptions on the skin.—Dr. Willan’s “Description and Treatment of Cutaneous Diseases.” Definition 1. (Page 12 of the First Edition.)

<sup>c</sup> Dr. Willan has four:—1. Lepra. 2. Psoriasis. 3. Pityriasis. 4. Ichthyosis. (See his “Description and Treatment of Cutaneous Diseases;” Order 2.) Dr. Elliotson places Ichthyosis elsewhere.

<sup>d</sup> See Dr. Willan’s “Description and Treatment of Cutaneous Diseases;” Order 2; Genus 3; Varieties 1 and 2; Plate 17.

<sup>e</sup> “Decocum Sarzæ Compositum.”

<sup>f</sup> Order 2; Genus 3; Variety 3.

the affected part first; and if that be cured, and the patient has no objection, we may go over all the rest. It is a complaint not attended by derangement of the constitution;—any more than the “scurf” of children. The causes of these affections, so far as I am aware, are not known. It may, now and then, arise in children from weakness; and it may be right to give tonics;—some preparation of iron or quina; and good nourishment; but, for the most part, I believe the treatment I have mentioned (Hydargyrum cum Cretâ, and mild diet) answers very well.

## SECTION II.—LEPRA.

The two other diseases in this class occur every day. They are diseases to which a great number of young men and women are particularly subject; and I think they are more common in the latter, than in the former. These two affections are very similar to each other; they run into each other; and, indeed, I think they might be considered as the same disease in different forms.

The first of these is called “lepra.” “Lepra” does not signify “*leprosy*,” according to the meaning attached to the ancient term. It is a different affection. It is by no means a loathsome disease;—consisting merely of red spots or patches on the skin, covered with scales. For the most part it does not affect the health, except so far as it may sometimes be connected with an inflammatory state; otherwise it is merely disfiguring and inconvenient.

*Distinctive Characters.*—In the disease denominated “lepra,” to distinguish it from “psoriasis,” the patches are circular, the margin is red, and elevated a little above the skin. The cuticle is sometimes very much thickened; and sometimes very white and silvery. The disease first appears in dots, varying in size from that of a pin’s head to that of a pea; and these dots become confluent, and form patches. It is about the outer part of the elbow, and below the knee, that these are most conspicuous. We see it also about the occiput, and behind the ears; and it will affect, more or less, the face and the whole of the scalp. The character of the disease is shown more in one part than in another; and it is a good general rule, when investigating cutaneous diseases, not to be satisfied with looking at one part of the body; for the disease may be *badly* characterized at one part, and extremely *well* characterized at another. It is best, in looking at cutaneous diseases, to examine the whole body; and, in doing so, we shall come to one part where the disease is so characteristic, that we may name it without any difficulty. The patches, in lepra, are sometimes as large as a crown-piece; and the disease much more frequently affects the extremities than the trunk; but we see it also very much about the head.

*Varieties.*—The most common form of the disease is that which is called “*lepra vulgaris*.” In this form the eruption usually assumes a circular form; the large patches, which are made up of an aggregation of small ones, being still more or less circular, and having around them a red margin, which is elevated. When they heal, they generally do so from the centre. This is the most common form. But I mentioned,<sup>a</sup> that now and then, the scales are very silvery. They are really as silvery as the scales of a fish; and then the disease is called “*lepra alphoides*.”<sup>b</sup> Now and then the scales are a little dark; and then it is termed “*lepra nigricans*.” In other words, it is sometimes very white; and sometimes black. That will do as well as remembering “*vulgaris*,” “*alphoides*,” and “*nigricans*.”<sup>c</sup> It is a great mercy that we have no other names given for the intermediate shades.

*Period of Life at which it occurs.*—I do not think I ever saw this disease in an infant, or in a child. We seldom see the disease in patients under ten or eleven years of age; and even then it is not so frequent as in the first stage of adult life.

<sup>a</sup> From λεπρος, *scabby*.

<sup>c</sup> See the previous Paragraph.

<sup>b</sup> See Page 406.

<sup>d</sup> From αλφος, *white*.

<sup>e</sup> For these three different forms of the disease, see Dr. Willan’s “Description and Treatment of Cutaneous Diseases;” Order 2; Genus 1; Species 1, 2, and 3; Plates 8 and 9.

From about seventeen or eighteen, up to thirty, the disease occurs more frequently than at any other period. Why this is I cannot tell.

*Causes and Duration.*—As to the cause, it is very common to discover none; but now and then it may be traced to a person having drunk cold water, or some other cold fluid, when overheated. This is a common cause of lepra, and a variety of diseases of the skin which are not contagious. It is a disease which will last a very considerable time;—perhaps two or three years; though sometimes it will go off in a few months. It is an affection which will recur; and now and then there is very great tingling, and very great heat of the skin.

*Contagious?*—I stated<sup>a</sup> that these diseases are not contagious; and that is allowed to be the case; but, two or three times, I have met with the disease contracted, apparently, from communication with another person labouring under it. It has happened to me (I am quite sure *twice*, if not *three* times) to see persons have lepra after sleeping with others affected with the complaint, or using their towel. These instances occurred in St. Thomas's Hospital. It might have been chance; but it so happened that a person had lepra, about a week or a fortnight after employing a towel which had been used by a patient affected with that disease; and, in another case, a young woman slept with a female who laboured under it; and she had patches as large as a half-crown. I cannot venture, therefore, to say that the disease is not contagious.

*Internal Symptoms.*—I always make it a rule to inquire in this, as in other chronic diseases of the skin, whether there are not some internal symptoms; and, in a large majority of cases, the patient complains of drowsiness, heat and pain of the head, and giddiness; and if we take away blood, we find it buffed, and perhaps cupped. This is an every-day occurrence; but it is by no means dwelt upon by Willan and Bateman as it should be. In fact, they were only forerunners to better writers on the subject. They were occupied, as historians, in pointing out diseases; rather than pointing out the pathology, or the rational mode of treatment. But if we make inquiry in cases of lepra, as well as of other diseases of the skin, we find the head affected at first, and frequently throughout the course of the disease. There are cases where nothing wrong can be discovered about the head; but even there we find the irritation and tingling very much relieved by bleeding.

*Treatment.*—In the treatment of this disease, it is improper to begin with any empirical medicine, till we have ascertained whether there is a sufficiently inflammatory state of the skin, to justify the adoption of antiphlogistic measures. Many cases will be cured by putting persons on low diet, and bleeding them from time to time. I do not know that mercury is of any use. Lepra, however, is often a venereal affection; and so likewise is lichen; and, in such cases, we fail in doing good, unless we exhibit mercury. But when the disease is of a syphilitic character, the redness is of a coppery hue, and the spots are hard;—in consequence of the disease approaching to a tubercular state. When these appearances are seen, it is better, whatever may be the assertions of the patient, to give mercury; for, on this subject, patients will tell all sorts of untruths, without the least hesitation. The hardness of the parts, and the copper hue, are sufficient to make us suspect that the lichen,<sup>b</sup> lepra, or psoriasis, is of a syphilitic nature. But when there is no decidedly inflammatory state, sufficient to make us bleed the patient, or if we have already used antiphlogistic measures to reduce the inflammatory state, then other remedies may be employed; but of the mode of their operation I am ignorant.

*Dulcamara and Arsenic.*—There are some of these remedies which, doubtless, deserve all the character that has been given them; and one of these is dulcamara. I have seen so many cases give way, under the persevering use of this medicine, that I have no doubt it is a remedy for the disease. A pint of the decoction may be given in the course of twenty-four hours; beginning with two ounces, three times a day, and then gradually increasing the dose. Arsenic, also, has very great

<sup>a</sup> See Page 403.

<sup>b</sup> See Page 369.

power over the affection. I have seen many cases yield decidedly, when a person took arsenic. I think that these two are, by far, the most useful remedies in the disease.

*Pitch.*—Some mention pitch as being serviceable; but I do not know that it has any particular power over the affection. If it has, I have not observed it; though I have made a patient swallow an ounce or two in a day. It is, however, perfectly harmless.

*Warm-Bath.*—The warm-bath is very useful; but if there be much irritation of the skin, the heat is unpleasant; and then I have not persevered with it. If the warm-bath be used, it should be in a decided manner. The vapour-bath is likely, on the whole, to be more beneficial than the warm-bath; but if either of them be used, it should be every day, or twice a day. There is nothing weakening in it, if patients do not keep themselves warm afterwards. The warm-bath is seldom used to the extent that is required.

*Local Applications.*—With respect to local applications, many persons wash the surface with a decoction of dulcamara; but we often find that the tar-ointment is very useful. If, however, there be much irritation, it is not proper; and zinc-ointment is better. Tar-ointment is certainly one of the best applications that I am acquainted with, in this disease;—provided it is not of a syphilitic character; and that we have employed antiphlogistic measures, as long as the blood was buffy and cupped, or the patient's pulse justified it. Dulcamara, or arsenic, should be united with it, as an internal medicine.

### SECTION III.—PSORIASIS.

*Characters.*—The other squamous disease is called “psoriasis.”<sup>a</sup> It bears a great affinity to lepra; and even runs into it. The difference between the two is, that in psoriasis the patches or spots are not circular, but more or less oblong; the margin is not raised; and it more frequently heals from the margin, than at the centre. In this disease the skin is very apt to crack; there are fissures in the skin, called “rhagades;”<sup>b</sup> and there is, for the most part, much more inflammation than in lepra. It is easy, in a great number of cases, to distinguish between these affections. In lepra the patches are circular, the margin is elevated, and there are no cracks; whereas, in decided psoriasis, the spots are oblong, the margin is not elevated, and there are fissures or cracks. But in intermediate cases, it is almost impossible to state, positively, whether it is lepra or psoriasis. They certainly run into each other. There is, very frequently, great irritation in this form of the disease. It tingles and smart severely. We have only, then, to discover whether the disease is attended by scales; and if it be, it is one of the three species to which I have now adverted. If it be “pityriasis,” the scales are very minute, coming as near to scurf as possible. If the scales be thick, the patches *circular*, the margin elevated, and there be *no* cracks, it is “lepra.” If, however, the patches assume an *oblong* form, and there be cracks, it is “psoriasis.”

In one form, there is little inflammation, which occurs in dots; it is called “psoriasis *guttata*.” If it occur in patches, it is called “psoriasis *diffusa*.” If any cause of irritation be applied to the skin, this may be aggravated. In washerwomen, for instance, the soap may produce this effect. Now and then it takes place, very locally, in the palms of the hands, or the soles of the feet; but chiefly in the palms of the hands; and it is then called “psoriasis *palmaria*.” The patches are oblong, and the margins not raised; and there are rhagades and fissures, which are so common that we rarely see the disease without them. The more severe the inflammation, the greater is the disposition to crack. Now and then this disease appears in

<sup>a</sup> From ψωρα, a scab.

<sup>b</sup> From ρηγνυμι, to break.

a form like that of worms; and then it is called "*psoriasis gyrata*."<sup>a</sup> I never saw this form of the complaint.<sup>b</sup>

*Psoriasis inveterata*.—There is one form of the disease which might be considered a pustular affection; namely, "*psoriasis inveterata*." Psoriasis sometimes lasts a great length of time;—in fact, till the whole body is covered with scales; so that scarcely an inch is free from it. The disease being very severe, those cracks which are peculiar to it, or characteristic of it, become very large; and produce a degree of oozing. The irritation of the skin is sometimes so great, that it not merely produces a diseased cuticle, but perhaps an oozing of fluid under the cuticle; so that psoriasis runs into lepra, on the one hand, and into those diseases which are characterized by a morbid secretion, on the other. Still the cracks and the occurrence of a scaly cuticle, show it to be a scaly disease. But we must look at these things as pathologists, and not as natural historians.

*Treatment*.—In psoriasis, we shall find antiphlogistic measures, particularly bleeding, of the greatest use. Many cases will be cured by moderate bleeding and low diet. I do not know that dulcamara is of the same use in this form of the disease, as in lepra;<sup>c</sup> but I have seen many cases cured by sulphuric acid, and by various other acids, perseveringly given. It is singular how large a quantity of the acids may be given. One would imagine that, being chemical substances, the quantity could not be increased to a great amount. It is commonly remarked how we may increase the dose of narcotics; but we know that the susceptibility of the body to any sedative agent, becomes less and less, the more frequently it is employed; yet we should not suppose that it would resist chemical agents. We may, however, increase the dose of sulphuric acid, properly diluted, to a great extent; and I have frequently done so in psoriasis with the best effect. But what I am anxious to point out is, the importance of antiphlogistic treatment, in all cases of this description, where it is needed; and to insist on the necessity of looking out for inflammation.

When the skin cracks, we sometimes find greasy applications of great use in softening the affected part; but, in a large number of cases, they cannot be borne. It is of great use, in the treatment of psoriasis, to prevent the patient from taking stimulants; for the disease is often kept up by stimulants taken as articles of diet. It is in vain to give acids, to bleed from time to time, or to give specific remedies (such as arsenic or dulcamara), unless the patient will submit to proper diet. If patients will take so many glasses of wine a day, they must expect the disease to be so much the worse. Alkalies, as well as acids, are said (and, I have no doubt, with truth) to be useful in this disease. The treatment of the disease, so far as the parts are concerned, is empirical. I have no idea how arsenic, and the other remedies mentioned, can act; but the treatment by bleeding (local and general), by low diet, and by the use of the warm-bath, is very rational.

<sup>a</sup> From *γυρος*, curved.

<sup>b</sup> For these different species of the affection, see Dr. Willan's "Description and Treatment of Cutaneous Diseases;" Order 2; Genus 2; Plates 11 to 16. In common language, the disease is called "dry or scaly tetter."

<sup>c</sup> See Page 405.

## CHAPTER IV.

## VESICULÆ.

WE now enter upon the consideration of those inflammatory diseases of the skin, which are characterized by the secretion of fluid under the cuticle. I shall begin with the description of those which are characterized by the secretion of a thin *watery* fluid: and, among these, of such as exhibit very *minute* collections. These diseases are termed “*vesiculæ*.” If the liquid be not water, but *pus*, the diseases are called “*pustulæ*;” if the secretion be water, and the collections are *large*, the affections are called “*bullæ*.” “*Vesiculæ*” and “*bullæ*” merely differ in point of size. The contents of a vesicle, therefore, are serous. They are also called “*limpid*;” but “*limpid*” is an indefinite word; and it is therefore better to say “*serous*.”

*Definition.*—A vesicle<sup>a</sup> is defined, by Dr. Willan,<sup>b</sup> to be “a small orbicular elevation of the cuticle; containing *lymph* [we had better say—“*serum*;”] sometimes clear, transparent, and colourless; but often opaque, whitish, or coloured.” The serum may be quite clear, or it may be rather opaque, or purple; and such an eruption as this may be succeeded, either by scurf, or by a scab. If the fluid be absorbed, and the cuticle which is detached rub off by degrees in minute portions, it is called “*scurf*;” if, on the other hand, the fluid be not absorbed, but the cuticle is ruptured, a “*scab*” is formed by the drying of the fluid, as it exudes. A scab may be formed either by serum, or by pus; therefore we may have a scab in vesicular diseases. A scab is defined, by Dr. Willan,<sup>c</sup> to be “a hard substance, covering superficial ulcerations, and formed by a concretion of the fluid discharged from them.”

## SECTION I.—MILIARIA.

*Characters.*—The first disease among those which are characterized by a minute collection of watery secretion, and of which I shall speak as having the most minute vesicles, is the “*miliary eruption*,” called, in Latin, “*miliaria*.” In this disease the vesicles are exceedingly numerous, and exceedingly minute,—about the size of millet-seeds (whence their name<sup>d</sup>). There is a slight inflammation of the skin, and a slight rash;—sometimes a little more; and then the disease is called “*red miliary eruption*.” If there be scarcely any, or what there is disappears, and there be only white vesicles, then it is called “*white miliary eruption*.” Some imagine, that the red variety is neither more nor less than scarlet-fever. Formerly the diagnosis was so imperfect, that many cases of *miliary* fever, were called *scarlet-fever*. However, if there is much inflammation, the skin will be red; if not, it will look white, from the number of these little vesicles. These miliary eruptions are, very frequently, nothing more than attendants upon other diseases. They will come on at an uncertain period of various cutaneous diseases. In measles,<sup>e</sup> and in scarlet-fever,<sup>f</sup> we continually see a little miliary eruption. I have frequently seen it on the hands, in the case of acute rheumatism. This eruption is most abundant on the breast, neck, and back; on the face and extremities it is less copious; and it will appear and disappear in uncertain order.

<sup>a</sup> The diminutive of “*vesica*,” a *bladder*.

<sup>b</sup> See his “Description and Treatment of Cutaneous Diseases;” Definition 3; Plate 1; Figure 10.

<sup>c</sup> Definition 3; Plate 1; Figure 4.

<sup>d</sup> From “*milium*,” *millet*.

See Page 382.

<sup>f</sup> See Page 358.

It is a thing of common occurrence; and the disease is easily recognized, in consequence of the extreme minuteness of the vesicles.

*Progress of the Disease.*—If the eruption be very copious, it is preceded by an unusual degree of languor and faintness, and a profuse perspiration; which perhaps accompanies it during the whole of its course; and which has a sour odour, or smells like rotten straw. There is sometimes a sense of heat, pricking, and tingling in the skin, before the eruption comes out; and even during its continuance. The vesicles at first are exceedingly small, and filled with transparent lymph; but, in about thirty hours, the lymph will become more or less opaque and milky. The tongue may be affected. It may be dark and red at the edges: and the papillæ<sup>a</sup> may be elongated. There may be aphthæ of the mouth and fauces. The duration of the disease is very uncertain. It is said to last from seven to ten days, or longer; but crop after crop may come out, and protract the case for six or seven weeks.

*Causes.*—This disease is supposed, by Bateman, to be nothing more than the effect of bad treatment. It was very common formerly, when lying-in women were kept in a heated room; when a number of blankets were placed upon them, thick curtains were drawn around the bed, and a fire was kept blazing in the apartment. Under all this it would have been strange if they had not sweated, and had a miliary eruption of the skin. It is supposed that there never was a specific disease of this kind; but that it was the result of over-excitement of the body, when there was more or less feverishness. There can be no doubt, I think, that there *is* such a specific disease as “miliary fever;” besides the “miliary eruption,” which may be produced by improperly stimulating a person by heat. Formerly in this country, at different times, there was a disease called “sweating sickness,” which was characterized by these very symptoms; and this disease now prevails, from time to time, in some parts of France; as in Languedoc, and Normandy. The disease has frequently prevailed in those places;—not sporadically, but as an epidemic. These are moist places; and the disease is there thought to be (as old writers in this country declare it was) contagious. The fluid from a vesicle has been inoculated without success; but, in the places I have mentioned, people declare there is no doubt of its being contagious. It affects adults, and particularly women. It is said to prevail only between forty-three and fifty-nine degrees, north latitude.

*Progress of Epidemic Miliaria.*—When it comes on in the epidemic form, it may (like most other diseases) be either mild or severe; so that it is divided into “benign” and “malignant.” The “miliaria benigna” is preceded by lassitude; frequently by pain over the eyes, and loss of appetite; but sometimes persons go to bed well, and wake in a profuse sweat. Very soon vesicles appear; and they sweat on till they die, or the symptoms cease. Now and then, before the eruption comes on, they complain (as people do in this country) of a sense of heat along the skin; and the sweatings are so profuse, that the patient is actually steaming. In the *violent* form of the disease, all the symptoms are intense; but the stomach is found to be particularly affected. What is called “gastro-enteritis” (an inflammation of the mucous membrane of the stomach and intestines) takes place; the sweats are very fœtid, and the patient smells exactly like rotten straw. The eruption generally comes out on the second or third day; and continues from two or three days, to two or three weeks. There may be merely scurf afterwards; the contents of the vesicles being absorbed. Or there may be an oozing from the vesication; and extensive desquamation may ensue. There may be violent headache, with giddiness and delirium. Such is the disease as it prevails in many parts of France. Several persons, in Paris, deny that there is any such disease;—exactly as other people will sometimes deny the existence of things, which they do not happen to see themselves.

*Treatment.*—The treatment of this disease, when it occurs (as *we* see it) from the effect of hot regimen, or a violent inflammatory complaint, consists simply in keeping the patient cool; and the whole will then subside. But *abroad*, when the

<sup>a</sup> From “pappus,” down.

disease prevails epidemically,—when they have what is called “the sweating sickness,” then it is frequently necessary to take away blood, to give a patient fresh air, and (I should think) to sponge him well. It is also necessary to pay attention to the inflammatory state of the stomach and intestines; and to take especial care not to give any thing that will irritate those parts;—to give neither emetics nor purgatives. I should presume that other cases might occur, in which it was necessary to support the patient well.

## SECTION II.—HERPES.

*Characters.*—The next disease of this description, is one of very common occurrence; but, as far as I know, is without any danger whatever. It is called “herpes.”<sup>a</sup> It is a vesicular disease, characterized by a great degree of inflammation at the base of the vesicles. It may be distinguished from some other vesicular diseases, by the great degree of inflammation with which it is attended. It is a disease on which we are continually consulted. Patients are very much frightened, and fancy they have some terrible disease coming; but we may easily quiet their fears. For the most part, very little treatment is required.

*Progress of the Disease.*—In most of its forms, it is an acute affection. It begins, perhaps, with general feverishness; and a great degree of smarting and tingling of the skin. The skin looks red, and clusters of vesicles then appear. It generally lasts from eight or ten days to a fortnight. There is not a large number of vesicles diffused over different parts; but they occur in clusters, and cluster after cluster will appear. Those eruptions which appear suddenly, on the chin (for example), are of this description. At first, the contents may be clear; but they soon become opaque and yellow. The scabs often seen about the mouths of children, are nothing more than herpes. Now and then it will occur around the whole body.

*Herpes Zoster, and Phlyctænodes.*—The patient is seized with a violent pricking, tingling, and smarting; and then there are seen vesicles, which form a cluster. This will go on, cluster after cluster being formed, till a belt is made. In common language this is called “shingles;” but in medical language it is called “herpes zoster.”<sup>b</sup> Now and then, the patient is a little indisposed at first; he has a little headache, and feverishness. But, frequently, there is no previous indisposition. The disease, when it occurs in separate clusters, is called “herpes phlyctænodes,”<sup>c</sup> but when it extends round the body, it is “herpes zoster.” This is the only difference in the two forms of the disease. In that form which runs round the body, there is a high degree of redness, and the vesicles are larger than in “herpes phlyctænodes.” It can make no difference, as to the nature of the affection, whether it occur in clusters or mere patches. There is, at first, smarting and tingling in both; and when this is all over, there is great itching.

*Herpes Præputialis and Labialis.*—This disease frequently appears in a very local manner; for instance, about the prepuce of the male. On the pudenda of women, also, little vesicles (which are herpes) will sometimes appear. They occur, too, about the lips and angles of the mouth; and children, from picking them, raise a scab; and thereby induce a sore, which lasts for a considerable time. If it occur on the prepuce, it is called “herpes præputialis;” but if it take place on the lip, it then receives the name—“herpes labialis.” Moderate antiphlogistic treatment, purging, the application of cold water, and some moderate astringent powder (to absorb the discharge), is the best mode that can be adopted. On the prepuce, it is frequently mistaken for a venereal affection; and patients often go to medical men in a great fright.

*Herpes Circinatus.*—Sometimes the patches will assume a circular form, with

<sup>a</sup> From ἔρπω, to creep.

<sup>b</sup> From ζαστήρ, a girdle.

<sup>c</sup> From φλύκταινα, a pustule.

the vesicles only on the circumference; and then it is called "*herpes circinatus*."<sup>a</sup> It is merely a number of vesicles spreading on the outward boundary. The great use of knowing the disease is, that we may not mistake it for a serious affection;—that we may be able to give a good prognosis.<sup>b</sup> The patches heal in the centre, and are commonly round; and hence it is called, by the common people, "*ring-worm*." The same treatment is applicable to this as to the preceding species; and, indeed, to every form of this disease.

*Herpes Iris*.—There is one curious species of the disease, where all the colours of the rainbow are present;—for which reason it is called "*herpes iris*." I have not seen it above two or three times. It occurs in circular patches; and each patch is of rather a different hue. It is generally seen on the back of the hands; and it occurred there in the cases that came under my notice. It is well described in Dr. Bateman's work. He says,—"The central vesicle is of a yellowish-white colour; the first ring surrounding it is of a dark or brownish red; the second is nearly of the same colour as the centre; and the third, which is narrower than the rest, is of a dark colour. The fourth and outer ring, or areola, does not appear until the seventh, eighth, or ninth day; and is of a light red hue, which is gradually lost in the ordinary colour of the skin. The iris has been observed only in young people; and was not connected with any constitutional disorder; nor could it be traced to any assignable cause." In fact, it is only inflammation of various hues.<sup>c</sup>—a remark which is illustrated by the appearance of this affection. It is a very *pretty* sort of disease. There is no difference in its cause from the others, and no difference in its treatment. Sometimes we can discover no cause for this affection; but it will come on after some little error in diet. There are concentric circles;—so that there may be a succession of these inflammations. Each of these forms of herpes may last a long time.

*Treatment*.—There is not the least danger in this disease; and the patient would do well if we gave him nothing. In that species of the affection which encircles the body, however, I believe it is a very good plan to cut the patient off from a little of his diet, and to give him a gentle dose of physic. One of the best applications to the part, is the oxide of zinc. It is well not to apply grease; for it irritates the part very much, but if we dust it with oxide of zinc, the fluid is generally absorbed, and the disease goes away. We may thus lessen the smarting, and the irritation; and lessen the duration of the disease. It would go away of its own accord; but we may mitigate it, and give considerable comfort to the patient.

### SECTION III.—ECZEMA.

*Characters*.—The next disease to which I will direct your attention, is very much like herpes;—so far as it is a vesicular eruption; but it differs from it, in having little or no inflammation. This disease is called *eczema*.<sup>e</sup> The decided difference between the two affections is, that herpes has a great degree of inflammation, and eczema none. We frequently see an eruption of vesicles on the skin, without any inflammation; they are larger than miliaria; therefore they are not miliaria, but eczema; and if there be inflammation attending them, we call it "*herpes*." That is all the difference. This eruption is very frequently seen on the neck or hands in summer. It may last only two days, or it may last a consi-

<sup>a</sup> From "*circus*," a *ring*.

<sup>b</sup> This variety of herpes, if it appear on the forehead and roots of the hair, may be mistaken for "*porrigo scutulata*;" but the vesicular character of the eruption, the regular course which it runs, and the hair not falling off, very readily enable us to distinguish it from the "*contagious ring-worm of the scalp*" (as "*porrigo scutulata*"<sup>e</sup> is called).—"*Cyclopædia of Practical Medicine*," Volume 2; Page 422.

<sup>c</sup> See Page 421.

<sup>d</sup> See Page 74.

<sup>e</sup> From *εκζω*, to boil out.

derable time. Any irritation of the skin may produce it. Intense solar rays may give rise to it; and stimulating acrid substances will have the same effect.

*Eczema Rubrum.*—The disease, however, is sometimes very severe;—extending over the whole body, and proving fatal. Perhaps we should hardly say it was the same disease; however, it is so considered by Willan. This form, called “*eczema rubrum*,” is chiefly induced by mercury. Every now and then, when persons have taken mercury, they have been seized with great heat of the skin and feverishness. A number of vesicles, larger than the miliary eruption, have appeared. They have spread all over the body; the cuticle has come off; fluid has exuded; and the irritation been so great, as to make the patient quite wretched. At the same time, the mucous membrane has become affected; and there is almost always cough. This, however, is not all. I have seen more or less disease of the throat; and frequently vomiting and purging;—owing to the mucous membrane, which runs from the fauces down into the abdomen, having also been affected.

*Treatment.*—In this severe form of the disease, which generally arises from some peculiar susceptibility of the constitution to mercury, it is necessary (of course) to leave off that medicine. It is well to give the patient the utmost supply of fresh air; to open the windows and doors; and to ventilate the room as much as possible. The smell from the discharge is exceedingly disagreeable; and it is necessary to apply something to absorb it. Nothing answers better than powdered zinc or calamine.<sup>a</sup> The latter is exceedingly mild, and never produces irritation;—so that we may sprinkle the patient well with it. It is also necessary to support the strength; to give nutritious broths, plenty of milk, frequently porter, and even wine. There is extreme debility of body induced; and I have seen several die from it. Inflammation will come on; and a difficulty arises between supporting the strength on the one hand, and subduing the local inflammation on the other;—so that we have to give, not wine or beer, but good broths; and to trust, on the other hand, to the depleting effect of leeches. The case is one which it is very unpleasant to treat; for, after giving the patient the utmost support we can,—tranquillizing his system by opium, and anxiously doing every thing possible,—after the lapse perhaps of six weeks, he dies; and it is not to be wondered at, when we consider the extent of skin which is in a diseased condition. It is not *always* mercury which produces this disease; but by far the most *violent* form is that induced by mercury. All the cases that I have seen, arose from that source. Other cases will occur, in which mercury has nothing to do with it.

*Eczema Impetiginodes.*—This affection is sometimes attended by the formation of a puriform serum. The disease runs into a pustular form; and is then likely to be chronic, and may last a considerable time. The divisions of the disease, therefore, are more or less arbitrary; for here we have a species of eczema which might, with equal propriety, be called “*impetigo*,” and therefore it is termed “*eczema impetiginodes*.”<sup>b</sup> There is scarcely any inflammation, compared with the intense redness of “*eczema rubrum*,” and sometimes none at all. In this local form of the disease, occurring acutely, the only measure requisite is to give the patient a dose of physic that will do him no harm. This form of the disease is really so nearly allied to pustular diseases, that it will save confusion if I defer further mention of it till we come to *impetigo*.<sup>b</sup> Every now and then we see a patient with vesicles in one part, and pustules in another; and therefore I think it better to describe it under the head of “*impetigo*.”<sup>b</sup> If we think proper, we may call it “*impetigo eczematodes*,”—just as we have “*eczema impetiginodes*.”

#### SECTION IV.—SCABIES.

Another disease which occurs more frequently in the form of vesicles than otherwise is “itch.” It is spoken of by Willan and Bateman as a *pustular* disease, and

<sup>a</sup> From “*calamus*,” a reed;—so named from its appearance.

<sup>b</sup> See Page 418.

it sometimes is so; but generally it is *vesicular*. Every body knows it by the watery heads; and therefore it may come under the head of "vesicles."

*Parts of the Body most Liable to it.*—The itch is called, in medical language, "scabies;"<sup>a</sup> and occurs chiefly about the wrists and ancles, the roots of the thumbs, and between the fingers and the toes; but if it be anywhere, we are almost sure to see it about the thumb. It occurs, too, on the front of the body, on the chest, and in the axilla. I do not recollect having seen it in the face. These are all curious circumstances, and the reason of them I cannot tell; but it is far more frequently seen at the roots of the thumbs than anywhere else; then at the wrist; next between the fingers, at the ancles, and between the roots of the toes; and next on the front of the chest. The disease is attended by an incessant itching. A Scotch king<sup>b</sup> is alleged to have said, that no subject deserved to have it, on account of the great pleasure derived from scratching the affected parts.

*Its Progress and Symptoms.*—I do not know how long the disease may last; it appears never to wear itself out. It is attended with no danger, except to young children. I have seen it excite such great feverishness in them, that if they had not been cured, it is possible that derangement of the alimentary canal, or of the head, might have been induced. If the patient scratch himself, the vesicles are ruptured. They then get dirty; a little blood (probably) exudes; and, between the dirt drying with the fluid, and a little blood oozing, we have small black heads. In children, we may often be mistaken as to this disease; for the irritation is such, that superficial inflammation to some extent occurs. Besides this, between and around the vesicles there is frequently common inflammation of the skin; and it will cause desquamation of the cuticle; so that the appearance of the disease is much disguised. In infants, too, the intense itching makes them rub their legs against each other; and that occasions the disease to be recognized with difficulty; but by looking at the roots of the thumbs, we shall see the vesicular form of the disease, and ascertain its nature.

*Its Varieties.*—If the eruption be of a watery character, the disease is called "scabies *lymphatica*;" if it be very rank,—resembling pimples, it is called "scabies *papuliformis*." These distinctions are not very important. It is of importance, however, to know that the disease is sometimes characterized by pustules;—large, full, flat-looking pustules; resembling any thing but the little vesicles which are seen in other cases. This is called, in common language, "pocky itch;" and is well known to the common people. In refined *medical* language, it is called "scabies *purulenta*." This is a species of the disease often mistaken;—from its being so unlike the common form of the affection. It occurs between the fingers, and at the back of the hands and wrists; where may be seen large pustules, of that description called "phlyzacious," attended with an inflamed base; and containing a thick yellow matter. When we have once seen the disease, there is no difficulty in recognizing it again. When there is great inflammation, we necessarily have suppuration induced. Even when the affection occurs in this severe form, it is generally found that, in other parts of the body, the vesicles are very small. It is only where there is great irritation, that this pocky form of the disease occurs. The general rule I formerly laid down,<sup>c</sup> is here applicable;—that by looking all over the body, we shall see the true form of the disease, in some part or other.

*Occurring after Fever.*—It is very common for itch to take place after fever. I have frequently seen this occurrence; but whether it came on spontaneously, or whether contagion had been applied before the fever occurred, I cannot tell. The *lymphatic* form is that which generally occurs in such cases.

*Causes.*—Some have imagined that this disease arose from a small insect; but that is only a part of the doctrine, that all contagious diseases depend upon animalcules. Some deny that there is any insect; some declare that they have picked an insect out, and seen it through a microscope; but others declare that they never

<sup>a</sup> From "scabo," to scratch.

<sup>c</sup> See Page 404.

<sup>b</sup> James the First of England.

could do so.<sup>a</sup> Though this is not a dangerous disease, yet it is a very troublesome one; and is held in great abhorrence. If we tell parents that their child has got the itch, they hold up their hands as if it had got the plague.

*It is Contagious.*—This is a contagious affection. The two last diseases which I have described (eczema<sup>b</sup> and herpes<sup>c</sup>) are not contagious; but the itch is very much so. It is, however, contagious in the *limited* sense of that word;—it cannot be communicated by the atmosphere. We may go as near to a patient labouring under itch as we please, without the least fear of imbibing the affection; provided we neither touch nor handle him. But the itch is not so easily caught by contact as might be imagined. I have frequently touched people,—taken them by the hand or wrist (not knowing that they laboured under the itch), without catching it. I once caught the affection; but then I was a little boy, and obtained it from the nursery-maid. By washing my hands after touching patients, I have always escaped contracting the disease. It is only by remaining in contact for some time, by sleeping with a person affected with it, or using something that the patient has touched for some time, that there is any chance of catching it. It is more commonly caught by sleeping with a person labouring under it, than by any other means. It is common for working men who come to London, and sleep in beds where the sheets have not been changed, to catch the disease. It is very common, also, among children who sleep together. It is said that this disease is sometimes caught from brutes which have the mange.

*Treatment.*—I need scarcely say that the great remedy for this disease is sulphur; but why, no one can tell. I do not believe that it has any effect when given internally. When I have employed it externally, I never found the cure accelerated by its internal exhibition. It may be employed in the form of vapour; or by means of baths, or in unction. In the latter form it should be rubbed in night and morning; and if a person do that, he will soon get rid of the disease. Some employ sulphur-baths. Some have impregnated water with sulphur; and say they have cured the disease in that way rapidly, and in a more pleasant manner than by rubbing in the ointment. It is said by some, who have had great experience in the disease among the lower orders, that it is more readily cured by what is called “sulphur *vivum*,” than by pure sulphur; if so, it is probably from the acrid matters which the former contains. If there be no great inflammation of the skin, the sulphur produces more effect if we add hellebore, or some stimulating substance. If the “sulphur *vivum*” answer better than pure sulphur, it is on account of some stimulating property.

[Scabies never tends naturally to a cure, but may last for years. The treatment consists in destroying the acarus as soon as possible. According to experiments made by M. Albin Gras, a concentrated solution of the hydriodate of potash kills this insect in the shortest time. It lives sixteen hours in vapour of burnt sulphur; three hours in water; two hours in olive-oil; one hour in the acetate of lead; one hour in pulverized brimstone; three quarters of an hour in lime-water; twenty minutes in vinegar and spirits of wine; twelve minutes in a solution of sulphuret of potash; and only from four to six minutes in a solution of hydriodate of potash.

<sup>a</sup> The immediate cause of the itch is now ascertained to be the presence of an insect,—the “*acarus scabiei*,”—at least, the existence of this insect is now placed beyond doubt by the recent researches of M. Renucci; which confirm the former assertions of Avenzoar, Hafenreffer, Bonomo, Cestoni, Ingrassia, Joubert, and Moufet. The acarus is to be found, not in the vesicle, (as Gale asserted, and thus misled observers,) but at the end of a small reddish furrow, sometimes straight, sometimes crooked, about two lines in length; which begins at the vesicle, and finishes with the insect. A minute subcuticular spot is often perceptible near a distinct vesicle: on raising the cuticle with a pin, a small white corpuscle, which moves when lifted with the point of the pin, becomes visible; this is the acarus. The serosity contained in the vesicles does not appear sufficient to produce the itch, whilst the acarus immediately produces the vesicles; but it yet remains to be explained, why the itch is so easily caught by only touching the hand of a person infected with it; for it is difficult to extract the insect furrowed under the cuticle.—“*Library of Medicine*,” Volume I; Page 885.

<sup>b</sup> See Page 411.

<sup>c</sup> See Page 410.

The ointment of this latter substance, in the proportion of about half a drachm to an ounce of axunge, may therefore be considered as the best application to the affected parts. Half a drachm of the sulphuret of lime, mixed with a little olive-oil, and rubbed upon the palms of the hands twice a day, for ten or fifteen minutes each time, proves also an efficient remedy. Helmerich's ointment—composed of one part of the subcarbonate of potash, two of sublimated sulphur, with eight of axunge—generally effects a cure in ten or twelve days. The sulphur water-bath generally proves effectual in about twenty-five days, on an average. The fumes of the sulphur should be avoided: they may, however, become a useful auxiliary in aged persons. Should much inflammation occur, or if vesicular or pustular eruptions complicate the itch, all irritating frictions must be suspended, and tepid emollient baths employed. Even after the cure is effected, a few tepid baths will be useful.

To disinfect the woollen clothes of patients, they may be subjected to the fumes of sulphurous acid gas;—easily procured by the ignition of a rag dipped in melted sulphur.<sup>a</sup>]

## SECTION V.—POMPHOLYX.

*Classification.*—The last disease which we have to consider, among those that are characterized by vesification, is what is called “pompholyx” (“water-bleds”). Willan places this disease in a separate order;<sup>c</sup> and so does Rayer; while the only real difference is that, in those of which we have been speaking,<sup>d</sup> the vesicles are very *small*; while here they are very *large*. I cannot myself see the reasonableness of making a distinct order of diseases, when the symptoms are precisely the same, and the only difference is a difference of size. One might as well call a tumour by one name if it be as big as a nut, and by another if it be as big as the head. However, if the vesicles be very large, they are called “bullæ;”<sup>e</sup> and because there are sometimes large vesicles in erysipelas, Willan and Bateman have placed that disease in the order “bullæ;” but as there are frequently only *small* vesicles (and indeed vesicles do not appear essential to erysipelas at all), I have considered it, as Rayer does, under the order “exanthemata.”<sup>f</sup>

*Characters of.*—When there is a very large elevation of the cuticle,—a large collection of water, the disease is called “pompholyx.” A vesicle appears on the skin out of health; which, instead of being small, as in eczema,—is large; and sometimes there is inflammation with a smarting and tingling sensation round it, as in herpes.<sup>g</sup> When it breaks, an excoriated surface is exposed; and a scab is formed of the fluid and cuticle together.

*Causes.*—It was imagined, formerly, that there was a particular fever attended by an eruption of large bullæ; and it was denominated “pompholyx;” but it is now doubted whether there is a distinct fever of that description. In common continued fever, and in other fevers well known, there may accidentally be a large bullæ—just as, in other cases, there are vesicles not larger than a millet-seed (miliary vesicles<sup>h</sup>). However, this disease—which is characterized merely by large blebs of water upon the skin—is not very common; and yet it can hardly be called uncommon. I may, probably, have seen about twenty cases of the disease. In many instances, it is really nothing more than large “eczema,”<sup>i</sup> or large herpes.”<sup>k</sup> All at once, a person will have one of these on his face or head, or both; and be much frightened. Here there must be something more than an inflammatory state; because I have treated them with antiphlogistic measures, and have failed entirely.

<sup>a</sup> “Library of Medicine;” Volume 1; Page 386.

<sup>b</sup> From *πρωτος*, a bladder.

<sup>c</sup> Order 4 (“Bullæ”).

<sup>d</sup> Miliaria (Page 408); Herpes (Page 410); Eczema (Page 411); and Scabies (Page 412).

<sup>e</sup> From “bullæ,” a bubble.

<sup>f</sup> See Page 397.

<sup>g</sup> See Pages 410 and 411.

<sup>h</sup> See Page 408.

<sup>i</sup> See Page 411.

<sup>k</sup> See Page 410.

*Pathology.*—[The pathological condition giving rise to this form of eruption, consists (as far as has been ascertained) in an inflammation of the *rete mucosum*, or upper surface of the cutis; by which a more copious secretion of serous fluid takes place, than can be transmitted by the cuticle;—thus causing its separation and elevation. In proof of this we may mention, that the *rete mucosum* remains adherent to the cutis; and is not detached with the cuticle;—as happens when this latter is forcibly torn off. The inflammation which gives rise to the formation of bullæ, may also be considered to exist in a higher degree than in erythema; for a higher degree of irritation converts erythema<sup>a</sup> into bullæ.<sup>b</sup>]

*Varieties.*—Bateman describes three varieties of this affection:—1. “*Pompholyx Benignus*.” ‘There is no great harm in that. 2. “*Pompholyx Solitarius*”—because there is only one. 3. “*Pompholyx Diutinus*”—because it is chronic. It is almost a pity to make these names; for who would conceive that there was much difference between “*pompholyx benignus*” and *solitarius*?” If it be “*solitarius*,” it is likely to be “*benignus*,” and it is not easy to see why sometimes it should have one name, and sometimes another. It is well to recollect, simply, that the disease may come on with only *one* vesicle; or that there may be *several*; and it may last for a *short* time only, or for a *long* time. It is very properly called “*diutinus*,” but we might as well call many other inflammations by the same term; for many last for a long time. I do not know why the term “*chronic*” should not be employed. Remember, then, that large vesicles on the skin, occurring as an idiopathic affection, are called “*pompholyx*.” Sometimes there is only one of these bullæ; and sometimes a succession of them; and persons will have them month after month. I have seen all these forms of the disease. A patient in the hospital for some other complaint, all at once, has a great bleb on his foot; and we have only to prick it, and away it goes. There is no other treatment necessary. But “*pompholyx diutinus*” is a very obstinate sort of complaint; and I never saw any thing do good in it. I have seen it occur under two forms;—the one in a worn-out constitution; where bleb after bleb appeared on the skin, which cracked and oozed like a sore; and then, when the body was one mass of these, the health gave way, and the patient died. In the other cases which I have seen, it came on in regular succession. I recollect the case of a woman who, once a month, had some large bullæ on her face. They were attended with considerable smarting. The fluid which oozed from them, produced inflammation wherever it went; it then dried up; and the cuticle healed.

*Treatment.*—That form of the disease which occurs in a worn-out constitution, requires to be treated by soothing measures. We must exhibit opium and moderate astringents; sprinkle calamine (to suck up the discharge); and support the patient well, by means of wine, bark, and good nourishment. In other cases, where there is no debility, we should attempt to treat the patient on antiphlogistic principles. I did so in the case of a woman, where the disease came out once a month; but the success was very limited. The irritation certainly was diminished; but the eruption came out again. By looking out for local disease, and attempting to cure it; applying the warm-bath; and, if any phlogistic state of the system occurred, taking away blood,—we should be doing what reason dictated; but more than that I cannot say.

<sup>a</sup> See Page 375.

<sup>b</sup> “*Cyclopædia of Practical Medicine*,” Volume I; Page 334.

## CHAPTER V.

## PUSTULÆ.

WE now proceed to another order of diseases of the skin; in which the secretion that takes place under the cuticle, is pus.<sup>a</sup> Several important diseases are found in this order. There is one, for the most part, of a chronic nature;—"impetigo."<sup>b</sup> There is another like that I have just mentioned; only it is contagious;—"porrigo."<sup>c</sup> Then there is another, called "ecthyma;" and there are also "cow-pox," "chicken-pox," and "small-pox." Thus we see that, except in the formation of pus, there is no agreement among these diseases. Some are *acute*, and some are *chronic*; some are *simple* diseases, and some are *contagious*; some of these contagious diseases occur but *once* during life, and others occur *frequently*. Porrigo may occur over and over again; but small-pox, as a general rule, does not occur more than once.

## a. Chronic Pustular Eruptions.

## SECTION I.—IMPETIGO.

*Characters.*—The first disease of the order "pustulæ," of which I will speak, is called "impetigo." I speak of it first, because it is closely connected with eczema.<sup>d</sup> Eczema, which is for the most part a chronic disease, is characterized by small watery vesicles; and frequently, instead of clear lymph, the fluid is almost puriform. Sometimes it is *altogether* puriform; and, in this latter case, we call it "impetigo." The two diseases run completely into each other.<sup>e</sup> Neither eczema nor impetigo is in the least contagious. We may touch or sleep with a person labouring under them, or inoculate with the fluid; and no disease will arise from it;—at least, nothing more than irritation.

*Varieties.*—This disease will occur, sometimes, in circumscribed patches,—just as in the case of herpes;<sup>f</sup> and then it is called "impetigo *figurata*;"\* and frequently there is inflammation around,—as in herpes.<sup>g</sup> Now and then the affection is very much extended over the surface; and is called "impetigo *sparsa*" ("sprinkled"). Now and then there is a thick scab; and then it is called "impetigo *scabida*." The affected parts look like the bark of a tree; only it is not a diseased cuticle, but a real scab formed of dry pus. Now and then there is so much inflammation around, that it is called "impetigo *erysipelatodes*;" and, occasionally, there is such irritation, that it is denominated "impetigo *rodens*" ("gnawing.") It is only worth

<sup>a</sup> Pustules are divided into four kinds; according to their size and figure. If a pustule be small and conically pointed, it is called "achor." "Achor" is said to take its name from *αχμ, bran*;—on account of the branny scales thrown off in the disease; but probably (as suggested by Blanchard) it is derived from *α, without*, and *χωρε, space*;—owing to the small size of the pustules. If, on the other hand, it be small, but flat, it is called "psyracium" (from *ψυδαξ, a small blister*); if it be larger, and have a sort of cellular appearance, it is called "favus" ("a honeycomb"); but if it be a fat, large, well-fed pustule, with an inflammatory base around, it is called "phlyzadium" (from *φλυζω, to inflame*). See Dr. Willan's "Description and Treatment of Cutaneous Diseases;" Definition 10; Plate 1; Figures 13, 14, 15, and 16.

<sup>b</sup> "Running Tetter."

<sup>d</sup> See Page 411.

<sup>f</sup> See Page 410.

<sup>c</sup> "Scald-Head."

<sup>e</sup> See Page 412.

<sup>g</sup> See Page 410.

\* This variety occurs most frequently on the face, and is identical with that form of eruption, known as *crusta lactea*, and confounded by some with the *porrigos*, but entirely distinct from true contagious porrigo, according to Bielt.

T. S.

while to remember, that it may occur in clusters; that it may occur with scabs, with a great deal of inflammation; and that it may occur with ulceration. I mentioned that, now and then, the fluid is watery, here and there, instead of purulent; and then it is called "*eczema impetiginodes*;"<sup>a</sup> and as there is pus in other parts, we shall be justified (if we think proper) in calling it "*impetigo eczematodes*."<sup>b</sup> These are the same diseases; only, according to the severity of the irritation, we have either pus or water poured out.

*Kind of Pustule in Impetigo.*—In the disease that I am now describing, the pustules are small;—just as the *vesicles* are small in herpes.<sup>b</sup> They are of the kind called "*psudracia*." It is of some use to remember this variety of pustules; because *one* disease has *one* species of pustule, and *another* a *different* kind. When the itch has pustules, they are of that description called "*phlyzacia*." The names given to these pustules are very hard words; and it would have been well had some others been devised; because it is sometimes difficult to distinguish the pustules of porrigo from these; and the difference in the pustules, is the principal means of diagnosis.

*Parts which it attacks.*—This disease, which is easily recognized,—on account of its being a pustular affection, and being characterized by the formation of pus in small flat pustules,—occurs particularly on the extremities. We continually see both men and women with this disease on the front of their legs; sometimes running all around, and sometimes upon the arm. If it be not properly treated, it will sometimes last for a very considerable time,—even for years. Sometimes there is a great degree of inflammation attending it.

*Treatment.*—The best mode of treating the disease, and the one that I have adopted, has been to regard it as an inflammation;—taking blood from the arm; applying leeches around the inflamed part, applying cold water, as long as that was agreeable; and then exchanging it for warm, and exhibiting mercury. This is an affection, in which, I am sure, a moderate use of mercury is necessary. All this, however, will be of no use, if the patient do not limit his diet. If he do not leave off wine and beer, and in some cases meat, the disease will not go away. It is a disease which, if not well treated, is exceedingly obstinate. If we adopt the plan I have laid down, although we may not *eradicate* the disease, yet we shall *lessen* it to a very great degree.

*Local Treatment.*—The chlorides are sometimes useful, and likewise the yellow-wash; but I have frequently seen them irritate the part. Altogether, the best local treatment is the application of some absorbent powder, (such as calamine or oxide of zinc,) and the constant application of cold or warm water. In the case of the leg, it is indispensably necessary that the patient should keep it, as much as possible, in a recumbent posture;—just as he would do in any other inflammation of the lower parts of the body. In the way of medicine, I am quite sure that mercury, exhibited very gently, is exceedingly serviceable.

*Treatment of Impetigo Eczematodes.*—In that form of the disease which is the link between impetigo and eczema,<sup>a</sup> the treatment would be precisely the same. We frequently see eczema of this kind behind the ears; running over the face, and down the neck; sometimes attended with a discharge of water, and sometimes with a discharge of pus. In fact, it may be either eczema or impetigo. When there is merely eczema, there is a great deal of scurf upon the part; so that when the secretion is stopped, the patient looks almost well; and then, when the part begins to run again, we have the neck looking moist and nasty; and having quite a different appearance. Whether it is eczema or impetigo, I believe antiphlogistic treatment, with the moderate exhibition of mercury, and the application of an absorbent powder, answers far better than any thing else.

Impetigo cannot be mistaken for any thing else except eczema; and they run very much into each other. It is a common disease. We cannot go into an hospital, without seeing cases of it. We might almost as well give different names

<sup>a</sup> See Page 412.

<sup>b</sup> See Page 410.

to rheumatism, if it ran down one shoulder, or occurred in both shoulders, or in one shoulder and one knee, as give different names to many of these cutaneous affections. It is very well to mention that they may occur in this way or that way; but to give them distinct names is quite absurd. In Plate 38, in Bateman's work, there is a representation of the disease called "porrigo;" which representation is nothing more than one of eczema; and the same may be said of the representation of "psoriasis," in Plate 11, Figure 2. If there be a watery discharge, it is called "eczema;" if it be matter, it is called "porrigo." Psoriasis,<sup>a</sup> eczema,<sup>b</sup> and porrigo,<sup>c</sup> run into each other.

## SECTION II.—ECTHYMA.

*Circumstances favouring its Occurrence.*—I now proceed to describe another disease, which also is not contagious; and is characterized by pustules called "phlyzacia;"—the large, round, well-fed pustules, with an inflamed base.<sup>d</sup> This is a disease which frequently takes place in a bad habit of body. The disease which I last mentioned (impetigo) takes place, occasionally, in a cachectic state of the system; but frequently it takes place in persons who are in other respects very well. The disease which I now describe, (ecthyma),<sup>e</sup> is one which commonly occurs after small-pox, measles, and scarlet-fever; and now and then after syphilis. Occasionally, I believe, it is itself syphilitic.

*Characters.*—It is characterized by pustules which are all distinct. In impetigo the pustules cluster; and when they are aggregated, they sometimes form clumps or clusters; and now and then they are diffused over a great extent. But in ecthyma, the pustules are all pretty distinct, and sometimes very large. Without knowing any thing of his history, we might think that the patient had small-pox. We continually see this affection in patients in the venereal wards;—it having come on in consequence of taking mercury. The pustules are all distinct, large, circular, and full of matter; not flat on the top, but globular. I have seen cases exactly like small-pox; and indeed I once knew a case sent to the hospital for small-pox, merely in consequence of the resemblance of the pustules. Now and then the pustules are remarkably large. When I say they are "full," I mean they are distended. Whether they be large or not, the discharge concretes into a dark-coloured scab. I recollect having had this disease when a child;—for I have had a taste of most diseases. I remember being very scabby for many months;—so that I was quite ashamed to be taken out for a walk. It is a disease which lasts a considerable time. Persons who say they have merely had gonorrhœa, frequently have an eruption exactly of this description.

*Diagnosis.*—It is very easily recognized. In the first place, there are *pustules*; therefore the affection belongs to the order "pustulæ."<sup>f</sup> We also see that they are *phlyzacia*;<sup>g</sup> that all of them are distinct; and that some of them run into scabs. For the most part they are not very numerous; but, when they are small, they may be so. In impetigo<sup>h</sup> they are circular, and not so distended; and have little flat tops. Sometimes in impetigo, they will congregate into one large mass; but in ecthyma the scabs are all distinct, though they may be large.

*Varieties.*—One of the varieties of this disease is called "*ecthyma vulgare*;" and it certainly gives a person a very vulgar appearance; but if it be a little darker, it is called "*ecthyma luridum*." (If lepra be dark, it is called "*lepra nigricans*;"<sup>h</sup> and it is a pity that the same adjective is not employed here.) If it occur in children, it is called "*ecthyma infantile*." We might as well apply a separate epithet to measles, accordingly as the affection occurred in infants or adults;—but this fondness for subdivision runs throughout Willan's arrangement. I mentioned that

<sup>a</sup> See Page 406.

<sup>d</sup> See Note (a) to Page 417.

<sup>f</sup> See Page 417.

<sup>h</sup> See Page 404.

<sup>b</sup> See Page 411.

<sup>c</sup> See Page 421.

<sup>e</sup> From *εκθύνω*, to break out.

<sup>g</sup> See Note (a) to Page 417.

the disease generally occurs in a bad habit of body; and if it take place in a very bad habit, it is called "*ecthyma cachecticum*." It will now and then occur (as is the case with almost all cutaneous diseases) with a sharp inflammation; and may last for a short time;—just like herpes,<sup>a</sup> or some other inflammations which produce mere serum, or which cause no secretion at all, but constitute a mere redness. They begin with inflammation of the skin, and feverishness; but the result of this disease will be suppuration. For the most part, however, ecthyma is a *chronic* affection, and lasts a considerable time;—the patient being very much out of health.

*Treatment.*—In these circumstances, the most eligible treatment is to strengthen the patient, in the best mode we can. Allow him wine, porter, meat, and fresh air, every day; and the warm-bath. If there be strength enough, I know that the employment of the *cold-bath* is very good. I would use the cold shower-bath in cutaneous diseases, when the patient's strength is able to bear it. Very frequently the disease is syphilitic; and, although the body is feeble, we find it necessary to give mercury, as well as to employ tonic medicines. Because we give mercury, it is no reason why we should not strengthen the patient, as much as possible. It is frequently a good practice to allow wine, porter, and meat in abundance; and to give tonics,—such as wine and bark; while, at the same time, we employ mercury. Sometimes we may alternate them.

### SECTION III.—RUPIA.

*Analogous to Ecthyma.*—This disease<sup>b</sup> very much resembles ecthyma; and, indeed, it appears to me to be exactly the same; but it is placed by Bateman in the order "*vesiculæ*,"<sup>c</sup> merely because the disease is serous instead of pustular; and Rayer places it in the order "*bullæ*," because the vesicles are large. It is called "*rupia*." It occurs in the same circumstances as ecthyma; the secretion soon becomes purulent; and, after a time, there are the same large black scabs; and no one could then tell whether the disease was rupia or not. For the sake of consistency, it may be necessary to make two diseases of these; but I am satisfied that rupia is nothing more than ecthyma;—that they are varieties of the same affection. All that is necessary to be remembered is, that ecthyma sometimes begins with serum; which soon becomes thick and turbid. There is another reason for making the two the same. In rupia there is frequently a scab, which becomes conical; so as to have exactly the shape of those shell-fish which stick to the rocks. This form of it is called "*rupia prominens*." In ecthyma there is frequently the same occurrence; the scab will assume exactly the same appearance; and the treatment of the two diseases is exactly the same. I cannot but think it trifling to separate them in this way. Although Rayer finds fault with Willan for subdividing these affections, yet he is over minute himself.

*Characters.*—The affection will occur in little children, particularly if they have been thrown out of health by measles or small-pox; and sometimes it will even occur after cow-pock. The vesicles are circular, with inflammation around them; and they have a black scab. They are distinct, too (just like the pustules of ecthyma<sup>d</sup>); and they are globular; only the contents are watery. Where the disease has been purulent from the beginning, I have seen dark scabs. Rupia is as frequently syphilitic as ecthyma; and just as frequently requires mercury. I would put ecthyma and rupia together;—just as I would put together lichen and erythema,<sup>e</sup> erythema and roseola;<sup>f</sup> and just as I would make no distinction between the orders "*vesiculæ*" and "*bullæ*."<sup>g</sup> I would have some one word to signify all the eruptions comprehended in those terms; from the size of a millet-seed, to that of a hen's egg. There are two kinds of rupia:—"rupia simplex," and

<sup>a</sup> See Page 410.

<sup>c</sup> Order 5.

<sup>f</sup> See Page 375.

<sup>b</sup> Deriving its name from *ρυπός*, filthy.

<sup>d</sup> See Page 450.

<sup>e</sup> See Page 408.

<sup>g</sup> See Page 369.

"*rupia prominens*;" but it is quite enough to recollect the word "*rupia*." It is a very common affection.

*Treatment*.—When this affection occurs in adults, they require support; and now and then we have to give mercury. With respect to local applications, I have never seen them do any good. The parts should be kept clean; and, when the scales come off, it is well to use a dressing of oxide of zinc, or Unguentum Hydrargyri.

#### SECTION IV.—PORRIGO.

The next disease that I will mention, and which is also a chronic affection, is of a contagious character. The three last mentioned diseases (impetigo, ecthyma, and rupia) are perfectly free from contagion;<sup>a</sup> but there is another,—a chronic disease, called "porrigo," which occurs particularly in the head; and is one of the most contagious diseases of the skin.

*Characters*.—In porrigo, the pustules are different from what they are in the two former diseases. In impetigo they are little pustules, and flat;<sup>b</sup> in ecthyma they are large globular pustules (phlyzacia);<sup>c</sup> but in porrigo (or "scald-head," as it is sometimes called) they are either small, with pointed tops; or large and flat;—that is, they are either acroes<sup>d</sup> or favi.<sup>d</sup> I have no doubt that many diseases which occur in the head, are called "porrigo," which are not. I think I have seen enough to justify the opinion, that many cases of *eczema* are called "porrigo."<sup>e</sup> But this disease, though it usually affects the head, may occur in various parts of the body.

*It is Contagious*.—The disease is *contagious*, but not *infectious*. It is commonly caught by children sleeping in the same bed, rubbing their heads upon the same pillow, or wearing the same night-cap. Frequently it is caught at school, by children putting on each other's hats or caps. Drinking out of the same mug, or giving a kiss (if any one could be tempted to do so) would, I should think, communicate the disease.

To show how very contagious these diseases are, I may mention the case of a barber, who had a child with a scald-head, and who kept a razor specially for shaving it. One day, by mistake, he shaved himself with it; and, although he had washed and stopped the razor well, and (like a true barber) put it into hot water first, yet, in consequence of using it to his own beard, the disease came out upon his chin, about a week afterwards. I saw it distinctly; and he told me the history of the case. Small circular pustules came out. We cannot too strongly impress upon the minds of people, the necessity of a child's dress being kept isolated in this affection; lest the disease should spread.

*Varieties*.—It sometimes occurs in distinct patches, and is then called "*porrigo scutulata*."<sup>f</sup> Now and then it occurs, with a great deal of inflammation, in distinct pustules,—not clustering together so much; and, these pustules being favi,<sup>d</sup> it is called "*porrigo favosa*."<sup>g</sup> Sometimes it has dry laminated scabs, of a yellow-whitish colour, containing a white scaly powder; and, from their resemblance to lupin-seeds, it has been called "*porrigo lupinosa*." In this form of the affection, the pustules are often very dry. The patches are full of hard grains, which are found to contain a great deal of lime; so that an earthy secretion takes place. They are not little globular pustules, but large and flat; and therefore they are called "favi."<sup>d</sup> A variety is mentioned by Bateman, under the name of "*porrigo furfurans*;"—where there are no pustules, but laminated scabs. I believe this is nothing more than *eczema*;<sup>h</sup> and I do not think it at all contagious.

*Porrigo Decalvans*.—This disease will sometimes occur without an eruption; so that we have an affection classed with those that are pustular; in which, never-

<sup>a</sup> See Pages 417 and 419.

<sup>d</sup> See Note (a) to Page 417.

<sup>f</sup> From "*scutellum*," a little shield.

<sup>b</sup> See Page 418.

<sup>c</sup> See Page 419.

<sup>e</sup> See Page 411.

<sup>g</sup> See Page 419.

theless, there are no pustules; but this inconsistency we cannot avoid. The hair will sometimes drop off here and there in patches, leaving the surface smooth; and this disease is said to be contagious. It is a very common affection; and is called "*porrigo decalvans*." I believe it is very common in the West Indies; and I have seen it in children who have come from thence. It is said to spread in schools (just like the other forms of *porrigo*) from the children wearing each other's caps. There is a doubt as to whether this should be called "*porrigo*." The skin is smooth; and I am sure, in many cases, this is the entire disease. Here is baldness without any reference to pustules, or vesicles, or an inflammatory affection. Sometimes half the head will be bared in this way; and sometimes the whole head. I once had a little patient, whose head was becoming perfectly smooth all over. I could do nothing with her.<sup>a</sup>

*Diagnosis.*—When an eruption occurs in the head, of a pustular kind, and lasts some time, we may be almost sure it is *porrigo*; but if we ascertain that the pustules are small (*acores*<sup>b</sup>), or large and flat (*favi*<sup>b</sup>), then we may be sure of the nature of the disease. It is said to occur in other parts of the body; but I do not recollect seeing it. *Impetigo*,<sup>c</sup> *eczema*,<sup>d</sup> and *ecthyma*,<sup>e</sup> are common enough on the extremities; but *porrigo* is much more particularly found on the head.

*Period at which it Occurs.*—*Porrigo* takes place far more frequently in children than in others; and it very often cures itself, when it is thought to be cured by medical means. It lasts for a certain time, and gradually declines. Children have it for a great number of years; and then, as they grow older, it ceases. There are diseases which are common to infancy, which gradually disappear as the subjects of them grow older; and scald-head is one of them; but I have seen persons labouring under it, who have attained their twentieth or twenty-fifth year; and who said they had had it all their lives.

*Treatment.*—As to the treatment of this disease, it is one of the most obstinate that can be taken in hand. There is often great inflammation;—so that, on placing the hand near the patient's head, we find great heat. We should therefore commence our treatment with antiphlogistic measures;—taking blood from the neighbourhood of the head, and applying cold water. These things are certainly useful, and appear to be indicated by common sense; but they are only useful to a limited extent; and, as I just now said, the affection is very obstinate. It is sometimes of great service to give mercury. "*Plummer's pill*"<sup>f</sup> first obtained its credit by curing a disease of this description. Dr. Plummer (Senior) of Edinburgh, states,<sup>g</sup> that he had a case of scald-head, for which he gave some common form of mercury; but the patient was no better. He then gave it mixed with a little guaiacum and antimony; and the patient presently got well. This pill was much employed by him afterwards, and others also used it; till at last it became well established; and

<sup>a</sup> The case is described in the "*Medical Gazette*;" Volume 7; Page 639.

The difficulties encountered in the study of the pustular diseases of the hairy scalp, have been greatly increased by the descriptions given by Willan and Bateman, under the titles of "*porrigo*" and "*porriginous eruptions*." They have described *porrigo* as a contagious pustule; and, at the same time, and under the same head, various eruptions, many of them not contagious, are jumbled together. Bielt, in his valuable oral lessons, delivered for the last twenty years, has unravelled the mystery. It is due to this eminent dermatologist to make this announcement; as others have not scrupled to publish, as their own opinions, the statements he delivered publicly many years ago. The "*porrigo lupinosa*" and "*porrigo scutulata*," as Bielt rightly observes, are alone contagious diseases, with peculiarly formed pustular eruptions. The others, termed by Willan "*porrigo favosa*," "*porrigo larvalis*," "*porrigo decalvens*," and "*porrigo furfurans*," are merely impetiginous or squamous affections of the hairy scalp. The denomination "*favosa*," was given by Bielt to one of the varieties of contagious *porrigo*, on account of the remarkable honeyed yellow colour of the incrustations, much more striking than any other; and it corresponded also with the name "*tinea favosa*," given by Alibert to that disease.—"*Library of Medicine*;" Volume 1; Page 400.

<sup>g</sup> In the "*Edinburgh Medical Essays and Observations*;" Volume 1; Page 46.

<sup>c</sup> See Page 417.

<sup>e</sup> See Page 419.

*Plummer's pill*" is now as well known as "*Dover's powder*." I much doubt whether it has any efficacy beyond an equal proportion of calomel. At any rate, I do not think that a grain of guaiacum can make any difference in a pill; and as to antimony, I believe, unless it produces nausea, it does not deserve to be considered a medicine. I have made comparative trials with calomel and "*Plummer's pill*;" and can say that I never found the latter at all superior to the former. However, mercury is often useful, and so also is sarsaparilla; as well as other medicines of that description.

*External Remedies.*—As to external remedies, besides antiphlogistic measures, astringents are very useful;—such as oxide of zinc and calamine. If there be but little inflammation, tar-ointment, united with that of nitrate of mercury,<sup>a</sup> is very serviceable; and sometimes an ointment of the red oxide of mercury.<sup>b</sup> These stimulating applications are often exceedingly useful. I have seen cases get well under the use of *coeculus indicus*. It is used to destroy vermin in the heads of children; and a drachm mixed with an ounce of lard makes a stimulating ointment, which is often beneficial. Sulphur, too, has been employed. A wash of the sulphuret of potassium is sometimes found advantageous in this disease. But, among external applications, when there is no great inflammation present, tar and citrine ointment<sup>c</sup> are among the best. I need scarcely say, that the head should be closely shaved, and kept very clean.

[Internal remedies are generally useless, unless the state of the constitution should require some gentle tonic;—such as infusion of gentian-root, taraxacum,<sup>c</sup> or hops, &c. When the disease has existed some time, blisters on the arm, and gentle aperient medicine, may be advantageously employed. When it is recent, and there are few pustules, it has been immediately arrested by cauterizing (with the nitrate of silver) the slight erosions of the skin, after the favous scab has been detached. But when the disease is of long duration, and of some extent, the appropriate means are alkaline and sulphurous washes, and acidulous lotions. The alkaline washes are made stronger or weaker according to circumstances. Ten or twelve grains of the *Potassa Fusa* in an ounce of distilled water, or one or two drachms of subcarbonate of potash dissolved in a pint of tepid water, are the best alkaline applications. The first lotion should be applied for a short time only; and the latter by means of moistened linen, constantly kept to the part. Alkaline ointments (one drachm of subcarbonate of potash to an ounce of fresh axunge) are also useful, and may be rubbed on gently after the wash. The ointment may be omitted, if it appear to soften the parts too much. Lotions of the sulphuret of potash,<sup>d</sup> containing one, two, or three drachms to a pound of distilled water, with an ounce of alcohol, may be substituted for the alkaline washes, should these prove inefficient. Gentle sulphurous douches, every morning, are also of great service. The acidulated washes consist of muriatic, nitric, or sulphuric acids, more or less diluted.

Solutions of the sulphate of zinc, of copper, of the nitrate of silver, or of the deuto-chloruret of mercury,<sup>e</sup> have been sometimes used with the best effects. The *Unguentum Hydrargyri Nitratis*, in some cases, improves the condition of the affected parts. Biett has lately employed, in "*porrigo favosa*," an ointment of the ioduret of sulphur, which merits the greatest confidence. We have seen it, in long-standing cases, greatly improve the state of the diseased skin, prevent the formation of fresh pustules, and cause the hair to be reproduced with the same appearances as that of the sound portions of the scalp.

During the treatment, tepid baths, and sometimes sulphurous water-baths, are useful adjuvants. The greatest care is to be taken to prevent the fluid which is exhaled from the excoriations, being carried over the adjacent parts;—the con-

<sup>f</sup> Dr. George Gregory.

tagious nature of this fluid having certainly some influence on the obstinate re-appearance of the favous pustules; and this is only to be prevented by great cleanliness, and the repeated use of weak alkaline washes. Should the irritation be intense, all stimulant applications ought to be suspended, and emollients substituted.

In very obstinate cases, the cauterization of the diseased surfaces, with some concentrated or rather diluted acid, has effected a cure. The acid should be passed over quickly with a feather, and water poured immediately on the parts, before the action of the caustic becomes too deep. We have lately seen kreosote succeed, when many other means had failed. The diseased parts are to be touched with a small hair-pencil dipped in kreosote; and dressings, with an ointment of a scruple of kreosote to an ounce of axunge, afterwards applied.<sup>a</sup>]

[The following aphorisms, by Dr. Graves, contain many valuable hints on the cure of this intractable disease:

“1. When the disease is of long standing, always insert an issue in the arm, before you attempt its cure. I have seen water on the brain, and other fatal consequences, from the neglect of this precaution.

2. If this disease has clearly originated from contagion, and no other evidence of derangement of the general health can be detected, we must not, from the mere presence of the cutaneous affection, infer a constitutional taint; and must avoid the common error, of making the poor children undergo a course of alterative medicines.

3. This affection, originating in contagious matter directly applied to the skin, cannot, like some varieties of lepra and psoriasis, (to which it often bears a great resemblance,) be cured by internal medicines; such as mercury, arsenic, and iodine, given separately or in combination (as in Mr. Donovan's new preparation).

4. When it occupies the hairy scalp, the common procedure of shaving the head is injudicious, for it adds to the irritation of the skin; and the scalp can be sufficiently exposed by cutting the hair as closely as possible, with sharp scissors.

5. The great object is to get rid of the morbid action which is going on, and which consists in an inflammation of the external surface of the corium;—an inflammation occurring in spots, and giving rise (in the first place) to an increased secretion of epidermis, which produces the scaly appearance of the parts affected; and (in the second place) to a very slight and scarcely perceptible oozing of moisture, which immediately dries into scales, and thus escapes notice;—being mingled with the scurf formed by the detached portions of morbid epidermis.

6. The cure must be accomplished by removing these scales, as far as that can be done by diligent ablution, without using any irritating degree of friction; and when the diseased portion of the skin has been thus exposed, we must next have recourse to some application which will destroy the morbid secreting surface. Formerly this was attempted by means of an endless variety of complicated formulæ, each of which had its advocates. The list may, however, be now reduced to a few simple remedies; and, in truth, with nitrate of silver, sulphate of copper, or strong tincture of iodine, every case of this disease may be cured.

7. I never use the solid lunar caustic, or sulphate of copper; but prefer a solution of ten, fifteen, or twenty grains to the ounce,—as the case may require. As to the application of this solution, it will not do to apply it (as is generally done) with a camel's hair pencil, *for it must be strongly rubbed into each spot*; for which purpose a small bit of sponge, covered with fine linen, and tied to the end of a quill or slender stick, should be employed. When a large portion of the scalp is affected, it will require some perseverance to apply this lotion in an effectual manner.

8. An application of this nature, when effectually done, must not be repeated oftener than once a week.

9. Immediately after it, the whole scalp must be covered with a dressing of

<sup>a</sup> “Library of Medicine;” Volume I; Pages 401 and 402.

spermaceti; which must be renewed at least four times daily;—so as to keep the head constantly moistened with it. The head is not to be washed for three days after the application of the caustic, or of the tincture of iodine; but then it may be well, but very gently, washed with yellow soap and water twice a-day;—taking care to cover (as before) with a spermaceti-dressing, after each washing.

In scaly diseases of the skin, it is quite surprising how much the cure is facilitated by keeping the affected parts constantly smeared with spermaceti, oil, melted suet, or even candle-grease. Without this aid, the use of caustics will often disappoint the practitioner.

10. When the above precautions have been taken, the cure will advance rapidly; and each succeeding application of the caustic-solution, or of the tincture, may be less severe.”<sup>a</sup>]

*Treatment of Porriago Decalvans.*—Stimulating applications are among the best. I should recommend the use of red oxide of mercury,<sup>b</sup> and other remedies of a similar description;—in fact, to treat it like the other forms of porriago.<sup>c</sup> The head must be kept well shaved all round, and very clean; and, by applying stimulating applications, the hair will at last be brought on. It is said that there is no doubt as to its being contagious; but I have not seen it so. It is by no means uncommon; but, like the other forms of porriago, it will cease after a time. I need not say that, in the various other forms of porriago, when there is a scab, in order to employ the ointment with effect, we should put on plenty of it; and the scabs, when softened, must be taken off. They should, however, be softened as much as possible at first; and, for this purpose, a poultice is sometimes necessary.<sup>d</sup>

*Acute Pustular Diseases.*—These<sup>e</sup> may be said to be all the *chronic* pustular diseases. Those which I mean next to speak of, are *acute*; and occur but once during life. They are diseases which we see every day; namely, chicken-pock, cow-pock, and small-pox. It is now believed, by a great many, that the two latter of these affections are one and the same; and some go farther, and think that even the chicken-pock is only a modified form of it. However that may be, these diseases are all exceedingly similar;—so far as they are *pustular*; so far as they are all highly *contagious*; so far as they are *acute* diseases; and so far as, for the most part, they occur but *once* during life.

## b. Acute Pustular Diseases.

### SECTION V.—VARIOLA.

*Its History.*—I will now consider a very important pustular disease; called, in English, “small-pox;” but, in medical Latin, “variola.” I understand that the word “pock,” or “pox,” is of Saxon origin, and comes from the word “*pec-cadl*,” which is derived from the word “*pocca*,”—a “bag” or “pouch;” or “*pocheha*,” which means the same thing,—a “little bag.” The terms “*small*” was added to it in the third or fifth century;—I suppose to distinguish it from “the *great* pox.” Some etymologists say it is called “variola” from the word “*varius*.”—“spotted;” or else that it comes from the Latin word “*varus*,”—“a pimple.” How the point is to be settled I do not know. The disease is called, in Spanish “*viruelas*,” and some derive this from the Latin word “*virus*.” The etymology, like the disease, is a mass of corruption. Mr. Moore has written

<sup>a</sup> “Dublin Journal of Medical Science;” Volume 18; Page 239. (November, 1840.)

<sup>b</sup> “Hydrargyri Binoxidum.”

<sup>c</sup> See Page 417.

<sup>d</sup> We would here direct the attention of the reader to “A Practical Treatise on Porriago (or Scald Head), and on Impetigo (Humid, or Running Tetter); with Coloured Engravings illustrative of the Disease. By the late Robert Willan, M. D. Edited by Ashby Smith, M. R. C. S.”

<sup>e</sup> Impetigo (Page 417), Ecthyma (Page 419), Rupia (Page 420), and Porriago (Page 421).

an admirable history of the small-pox,<sup>a</sup> and another of the cow-pock;<sup>b</sup> both of which works are exceedingly interesting, and well worth reading. He says that the word "*variola*" was first found in an old Saxon Chronicle, ascribed to Marius (Bishop of Vaux, in Switzerland); who says that a violent malady, attended with purging, broke out in Italy and France, in the year 570.

*Premonitory Symptoms.*—The disease, before the eruption appears, is marked by certain premonitory symptoms. The patient, first of all, is generally seized with languor, drowsiness, vomiting, and pain of the head and loins;—just as might occur in any other fever. Here the head is affected ("drowsiness" and "languor"); the stomach is affected ("vomiting"); and "the loins" are affected; as almost always occurs in common continued fever. There is pyrexia, universal feverishness, quickness of pulse, and also tenderness of the epigastrium; but the pain in the loins, and the tenderness of the epigastrium, are frequently most intense; being very marked in this disease.

*Appearance of the Eruption.*—After these symptoms have prevailed a day or two, there appear, first on the face, and then successively throughout the body and extremities, small red spots (papulæ;<sup>c</sup>) and these rise into elevated pimples, and these again into hard tubercles,—in the common acceptance of the word.<sup>d</sup> So that, first of all, you have mere red spots on the skin; these spots rise into what are commonly called "pimples;" and then these pimples become very hard (*tubera*). These pimples become pellucid; and, on the fifth day (counting from the first attack of feverishness, headache, and so on,) they become pustules. From being pellucid, they have purulent contents opaque and white; and those which are large, are at first generally depressed in the centre. This is worthy of notice. They are not perfectly filled at first; but are filled in the circumference more than in the centre.

When this eruption is taking place, if the individual be an adult, there is frequently a great tendency to profuse sweating; and if the patient be a child, there is a great tendency to epileptic fits. It is said that one fit forebodes a mild disease, whereas several forebode a severe one. Where there is but one fit, there is so little mark of severity of disease, that it often has been deemed a favourable symptom; but I should suppose, that if the child had no fit at all, it would forebode something better still.

*Period of Maturation.*—On the eighth day,—counting always from the first,—if there be much eruption, the face swells from the inflammation. If the disease be pretty severe, the cellular membrane beneath falls into more or less irritation, and secretes abundantly; so the face swells on that account. The same circumstance causes the eyes to close; and the continued extension of the irritation causes the mouth to "run," and the fauces to inflame. On the eleventh day, the pustules are at their height;—as full and as numerous as they will be; and the swelling of the face, the "running" of the mouth, and inflammation of the fauces subside; and then the hands and feet swell;—first the hands, and afterwards the feet. The spots spread down the body and arms, towards the hands and feet; and, as these parts suffer the last, so they swell the last; and when the swelling commences in them, the irritation has already begun to subside in the parts originally affected. The pustules are then said to "mature;" that is to say, they grow ripe and perfect.

*Secondary Fever.*—When this general suppuration has occurred, and the formation of pustules is perfect, then a fresh attack of feverishness occurs; and this is called the "*secondary fever*." That which occurs in the beginning,—ushering in the disease, and continuing for a little time,—lessens when the eruption comes on, and is called "*the primary fever*;" and when the eruption has gone on for a certain number of days, and the general irritation is lessened, a second attack of feverishness takes place. The eruption is now perfect;—all the pustules having attained

<sup>a</sup> "The History of the Small-Pox. By James Moore."

<sup>b</sup> "The History and Practice of Vaccination. By James Moore."

<sup>c</sup> See Page 366.

<sup>d</sup> See Pages 189 and 365.

their full development, and each pustule having become filled with matter, and of its full size.

*Decline of the Eruption.*—When the pustules begin to diminish, and the matter to be absorbed, the common people, especially old women, call it “the *turning*.” We continually hear, in practice, that the disease has “turned;” and the meaning of that is, that the pustules have begun to subside. The pustules on the extremities, as I have said, appear later than those on the face and trunk; and their contents, I should also mention, are more limpid. There is not that excessive inflammation which produces *pus*; but only a *puriform fluid* is secreted;—a limpid fluid rather than perfect pus; and in them the fluid is frequently absorbed altogether, without any exudation occurring. In the other pocks, throughout the body and the face, the matter very frequently *exudes*; but those upon the extremities, particularly the hands and feet, lose their contents entirely by *absorption*;—so that the elevated cuticle remains flaccid and empty. The pustules on the extremities, as they *come out* last, also “turn” last.

*Pits and Cicatrices.*—The pustules, too, when the matter escapes, generally dry into hard scabs. The matter exudes; a scab is formed of this dry pus; and frequently a little ulceration is found to take place;—so that a pit is left. The secretion is not merely superficial and cutaneous; but ulceration of the cutis, and even of the cellular membrane underneath, takes place;—so that marks are left. These pustules are nothing but so many minute abscesses; and, of course, there is more or less destruction of the parts, and a cicatrix is left on a small scale. If many of these run together, then a person is said to be “seamed.” There are whole tracts of loss of substance.

*Critical Days.*—The days, then, on which the changes take place, are first according to the *tertian* type, and afterwards the *quartan* type. The day on which the disease begins is the first day; then on the third (which is according to the *tertian* type) the pustules make their appearance; and on the fifth day (still according to the *tertian* type) perfect pustules are formed. The eruption begins as a little spot. This is succeeded by an elevation, which afterwards becomes hard, and contains a limpid fluid, which, on the fifth day, becomes perfect pus. From that time the *quartan* type commences; on the eighth day, if there be much eruption, the face swells, the eyes close, and the mouth “runs;” and on the eleventh day the pustules are all at their height, and there is no farther aggravation of the eruption. This enumeration will assist the memory.

*Variola Discreta.*—The disease is generally divided into two varieties; the one called “distinct,” and the other “confluent.” In what is called “distinct” or “discreet” small-pox, the pustules do not touch each other. The pyrexia, or feverishness, is of that kind called “inflammatory;” and is attended with a pretty strong pulse, and great heat of the body. The pustules are comparatively few in number; and are all detached. Perhaps there may be very few pustules;—only one, two, three, half-a-dozen, or a dozen; but if there be more, still they are detached. They all look healthy, and have a rose-coloured base;—showing a healthy inflammation. Their contents are good, “laudable,” “praiseworthy” pus.<sup>a</sup> The fever, in this form of the disease, lessens when the eruption comes out; and when the eruption is complete, the feverishness is nearly gone. The disease is mild but perfect.

*Variola Confluens.*—In the other form of the affection, however, (which is called “*variola confluens*,”) the pustules are very numerous, and run together. The feverishness is infinitely more violent, and rather of a typhoid character; the pulse is not so strong; the patient is exceedingly weak; and there is delirium. There is often so violent an affection of the head, that it produces coma; and the eruption not unfrequently begins early,—even on the second day. The pustules are not only far more numerous, but they are smaller, flaccid, and not filled as they should be. Their quality also is bad; for, instead of containing a creamy “*lauda-*

<sup>a</sup> See Page 100.

ble" pus, the contents are brown,—perhaps thin and serous; and perhaps there is a brownish ichorous fluid, rather than genuine pus. They not only run together; but, from not being well filled, they appear more or less flat.

*Attendant Symptoms.*—The feverishness, in this form of the disease, is very little lessened on the appearance of the pocks; and at the end of the eruption it is aggravated very much. Secondary fever, of a very violent character, comes on. The symptoms occurring in other parts, are also very severe. There is much more "running" of the mouth, and much more inflammation of the fauces, than in the distinct form; and, in infants, there is sometimes violent diarrhœa. In this latter instance, the lower part of the alimentary tract suffers great irritation. Frequently, too, between the pustules, there are petechiæ, vibices, and ecchymoses;—there are, in short, red, dark-coloured spots, of various sizes. Sometimes there is bloody urine; and sometimes blood appears in the motions. The secretions are very unhealthy; and there is an exudation all over the body; so that the person emits a very offensive smell. Now and then, patients labouring under this form of the disease die rather suddenly. The consequences of this species of the disease, too, are more severe than in the other form. In fact, it is "*variola confluens*" that, for the most part, leaves such terrible consequences; such as blindness, phthisis, and diarrhœa;—the latter of which ends in ulceration of the intestines.

*In Negroes.*—It is said (but I do not know the fact from experience) that negroes have a horny, warty, small-pox; and that the eruption is minute in size. Fibrin is effused into the pocks; which give them a hard warty appearance.

*Complications.*—[Such are the ordinary phenomena of the natural small-pox, in its distinct and confluent forms, when it occurs to persons previously in good health, and of sound constitution. But it must be remembered, that this disorder may attack those who may be labouring, at the time of seizure, under some other disease;—such as pneumonia, hooping-cough, hepatitis, or consumption; and, further, that these and other disorders may come on, unexpectedly, at any period (early or late) during the progress of small-pox. An infinite variety of accidental symptoms, may thus be superadded to those regular symptoms already enumerated. Besides which, small-pox may occur to persons of a weak habit, or in constitutions exceedingly exhausted, and unable to cope with a disease of such severity. It may occur, for instance, to those who have but recently recovered from a severe typhous or scarlet fever. In these circumstances, we observe a very tardy eruption; collapse without advance of eruption; or, in a case somewhat more favourable, an abundant formation of large blebs, containing a thin ichor, with a very tedious and hazardous period of convalescence. To this latter form of the disease, the old writers gave the name of the "*watery or bladder-pock*."] <sup>a</sup>

*Occurs only once.*—The disease rarely occurs more than once during life; and, although we may all see instances of its secondary occurrence, yet these are exceptions to the general rule. Like measles, however, and scarlatina, it may occur more than once.

*Co-existent with Measles.*—It was a dogma of John Hunter (an assertion without proof) that no two specific diseases could exist, at the same time, in the same body; but this is untrue. We see persons labouring under itch and syphilis at the same time; and there are plenty of instances on record, of small-pox co-existing with measles and cow-pock; though, in general, one disease runs its course in the body, and then the other. It is mentioned, in the "*Edinburgh Medical Commentaries*," that measles and small-pox occurred simultaneously in sixteen children. Out of forty-three children who were inoculated, sixteen were at the time labouring under measles; and both the diseases went on together. This occurrence took place at the Foundling Hospital in Dublin.

*Effects.*—Pustules frequently form around the eyes, and on the cornea itself; and there is often ophthalmia;—which not unfrequently (in the violent form of the disease) produces albugo, or staphyloma. Formerly, a great number of persons

<sup>a</sup> "Cyclopædia of Practical Medicine;" Volume 3; Page 742.

were rendered blind through the small-pox. When the disease is over, it frequently leaves scrofula. Persons may have enlarged glands of the neck; or they may have enlarged mesenteric glands; or they may have phthisis. Frequently it leaves rupia and ecthyma. Diarrhæa, too, is not unfrequently left after it; and the mucous membrane of the intestines sometimes falls into chronic inflammation.

Among the mucous membranes, those of the larynx and trachea frequently suffer much. Many children die, from the upper part of the trachea being blocked up with a thick tenacious mucus, and much swollen. It is a point to which Mr. Alcock, the surgeon, has particularly attended; and in consequence of having had my attention directed to it by him, I have frequently examined the larynx of children who have died of this disease; and its state has been such as to astonish me. There has been great inflammation; and so great an effusion of thick stuff, as very nearly to block it up.

*Morbid Appearances.*—[The following is a summary of the principal results deducible from the investigations of Dr. Petzholdt, into the morbid appearances found in the bodies of persons dying of small-pox:—

- “ 1. There occurs softening of the undermost layers of the cuticle; and, at a later period, destruction of the connection with the cutis.
2. Orifices are never observable in the cuticle covering pocks.
3. What is called the ‘pit’ or ‘umbilicus,’ is produced by the retention of the cuticle by the excretory ducts of the cutaneous glands.
4. All pocks have not a pit or umbilicus.
5. The pit, or umbilicus, never exists in pocks seated on the palm of the hand or sole of the foot.
6. On the base of the pock, and consequently on the surface of the cutis, the orifice of the gland can be seen; except in the palm of the hand or the sole of the foot.
7. The portion of the surface of the cutis not covered with pocks, is also in a morbid condition.
8. The vessels at the base of the pock exhibit marks of inflammation; those at its circumference, marks of congestion only.
9. The (so called) ‘wind-pocks’ are by no means empty.
10. The cutaneous glands are generally swollen in small-pox.
11. The excretory ducts of the glands, when destroyed, as well as the hairs that fall out, are regenerated.
12. The mucous membranes of persons affected with small-pox, often exhibit inflammation, with the formation of vesicles and ulcers.
13. Vesicles and superficial excoriation are met with on the tongue.
14. On the pharynx and back part of the mouth, there are never pocks; but the glands there seated are much distended, and have very wide orifices.
15. There occurs softening of the epithelium of the œsophagus, rising into pustules.
16. At a later period, the epithelium is completely destroyed.
17. Ulcers are met with in the œsophagus; but never with *perforation* of the proper mucous coat.
18. No pocks are found in the stomach and intestinal canal; but there occurs destruction of the papillæ of the mucous membrane, particularly in the small intestine.
19. There is often dendritic vascular injection of the mucous membrane of the alimentary canal.
20. Ulcerated parts are occasionally found in the mucous membrane of the nasal fossæ.
21. Vesicles form in the trachea.
22. Ulcers occur in both larynx and trachea.
23. The mucous membrane of the genital organs is free from pocks; except at its junctions with the external skin.
24. On the serous membranes nothing more is (in general) to be seen, than what is found after their inflammation in other diseases.

25. In a few cases, an eruption was found on the serous coverings of the spleen and liver.<sup>a</sup>]

*Causes.*—The cause of this disease, I believe, is in most instances a specific poison, generated by an individual labouring under the disease. Children sometimes have it without there being any possibility of tracing infection; but for the most part we can do so. It is a disease which is *infectious* as well as contagious.<sup>b</sup> There is no occasion to touch the patient labouring under it, or any thing he has touched; to be near him is quite sufficient. One reason for thinking that it always arises from another individual labouring under it is that, in Denmark, the disease was made to disappear for many years, by practising vaccination on every individual; but at last the inhabitants grew careless; and, on their being visited by persons labouring under the affection, it again broke out. If, however, the two diseases be the same, the argument falls to the ground; for if the cow-pock be merely modified small-pox, then these are merely instances of the disease occurring but once.

*All Persons Liable to it.*—Almost all persons are liable to take the disease;—so liable, that it is hardly right to say that a predisposition is required. From the few who escape if the poison be applied, it is a better mode of expression to say, with regard to those who will not take it, that “they are *indisposed* to it,” than to say that “they are *not predisposed* to it.” The only thing wanted, is the absence of an indisposition. Persons have been known to escape this disease for forty or fifty years, and then to have it. The same circumstance occurs with regard to hooping-cough, and other contagious diseases. It is supposed that the predisposition to it, is strongest in early life; but I mentioned formerly, that this is hardly proved; because most persons take the disease, if they have not had the cow-pock, in infancy or childhood; and therefore there are but few adults left to have it.<sup>c</sup>

*Its Occurrence in the Fœtus.*—Like syphilis, it may occur in the fœtus. The mother may give syphilis to a child in utero, and also the small-pox; and, in the latter affection, it is singular that the mother may communicate it to the child, without having it herself. Dr. Jenner published<sup>d</sup> instances of two women who were exposed to the contagion of small-pox, a few days before delivery. Both women were, I believe, exposed to it by *infection*; but one woman had had the affection formerly, and the other had been inoculated;—so that both had acquired an immunity. Neither of the mothers had the disease a second time; and, therefore, they served merely as transmitters of the poison to their children. In the one instance, the disease appeared in the child on the seventh day after birth; and the other female brought forth a child covered with the small-pox. Dr. Mead, in his “*Treatise on Variola*,” mentions a similar fact. However, this has not always been the case; for Sir George Baker mentions that two women, who took the disease during pregnancy, brought forth children perfectly healthy; and the latter never had small-pox till they were inoculated; which did not take place till they were three years old. I do not know whether a woman can give syphilis to a child, without the disease affecting herself;—whether she can have the poison conveyed to her system by a man, and yet have no symptoms of the disease, and nevertheless produce a child affected with syphilis. In my experience, wherever syphilis has appeared in a child at its birth, or soon afterwards, the mother has shown syphilitic symptoms, either then or soon after. It is to be remembered, however, that we have no immunity from syphilis. We have immunity from small-pox and cow-pock, in consequence of the disease having occurred previously; and when immunity can be produced from a poison, then the system may transmit it, though perfectly safe itself.

*Period of Incubation.*—As to the period at which the disease appears after exposure to the poison, the late Professor of Botany in Edinburgh (Dr. Rutherford) used to say, that a party of soldiers were exposed to it, in the natural way; and

<sup>a</sup> “British and Foreign Medical Review;” Volume 5; Page 479.

<sup>b</sup> See Page 300.

<sup>c</sup> See Page 384.

<sup>d</sup> In the first volume of the “Medico-Chirurgical Transactions;” page 271.

that the interval between their exposure, and the appearance of the disease, varied from twelve to fourteen days. Dr. Fordyce, who paid great attention to this subject, said that the period which I have now stated was the common interval. However, it is certainly known sometimes to come out earlier.

*It is frequently Epidemic.*—Like other infectious diseases, it is very frequently epidemic; and it is more frequently so at the vernal equinox, than at any other time. It is said, by Sir Gilbert Blane, to resemble measles and hooping-cough, in being more fatal during an epidemic than at any other time. After it has been absent some time, it is also more severe than at other periods. It is also observed to be like all other epidemics in another respect;—those who have it first, have it most severely.

*Opinions of the Ancients on the Contagion of Small-Pox.*—It is said that this was not known by the ancients to be a contagious disease: and, indeed, they confounded measles, scarlet-fever, and small-pox together.<sup>a</sup> Rhazes, an Arabian, and one of the oldest writers on the subject, ascribes it to the fermentation which the blood undergoes, when the youth is becoming a man. Sydenham (who has given so perfect a description of small-pox, that it can never be surpassed) had no idea that it was a specific contagion. He thought that scarlatina was most prevalent in the autumn; and ascribed it to a moderate effervescence of the blood, arising from the heat of summer. He entertained much the same opinion of measles and small-pox. I mentioned<sup>b</sup> that Gadbury, the astrologer, wrote (without fear of being laughed at) that plague was not more infectious than the small-pox. Then another worthy man (Etmuller) who is much quoted by German writers, says that no doubt small-pox and measles take place from the child drinking morbid nourishment in the uterus; and from sucking it in the milk after birth. He says,—“It is not probable that those who assert that measles and small-pox arise from copulation after conception has taken place, are correct; and therefore I suppose that the foundation of measles and small-pox lies in the milk, which the child takes first when in utero, and then afterwards when born.”

*Influence of the Atmosphere.*—Small-pox was distinctly declared to be contagious by Boerhaave; who mentioned contagion as the only cause of it. But though nobody now doubts that it is contagious, yet its spread is greatly influenced by certain states of the atmosphere. Violent cold will check an epidemic small-pox. The wind called “harmattan”<sup>c</sup> stops small-pox, just as it does the plague; and it is said to prevent the effects of inoculation; so that if we inoculate when that wind is blowing, it is a fruitless task. I mentioned<sup>d</sup> this particular circumstance, when speaking of contagion in general, in order to show what influences are exerted on it. Sir John Pringle says, that the small-pox was carried by some troops, on one occasion, to the camp; but, in consequence of some peculiar state of the atmosphere, it would not spread. Van Swieten mentions a similar fact. Dr. Odier, a physician at Geneva, mentions that when this disease was not epidemic, it would not spread by contagion. When children had the disease by inoculation, if they were carried about the streets, and brought into contact with other children, during the eruption, there was not a single instance of a child catching the disease. Sir James M-Grigor says, that when the disease was prevailing extensively at Bombay, in the neighbourhood of his barracks, although there was the freest communication between the inmates of the barracks and the surrounding population, yet no person about the barracks caught the disease. When we are considering whether a disease is contagious or not, we must set no value upon the circumstance of certain states of the atmosphere putting a stop to it. Contagious diseases, in this respect, are in the same predicament as those which depend altogether upon atmospherical influence. That it is a contagious disease cannot be doubted, when we reflect that it will habitually occur to children, when their parents will not allow them to have the cow-pock.

*Inoculation.*—Small-pox is communicated artificially by inoculation; because the

<sup>a</sup> See Page 387.

<sup>b</sup> See Page 307.

<sup>c</sup> See Page 255.

<sup>d</sup> See Page 309.

disease which then arises, is much more mild than that which occurs naturally. The effect of inoculation is to lessen the number of pustules; and thus to lessen the general violence of the disease. The effect of vaccination upon the disease, if it do not prevent it altogether, is rather that of lessening its duration. Inoculation produces the disease with a far smaller number of pustules, and less general irritation; whereas, if a person have small-pox after vaccination, the disease goes on in the usual way for a certain time; and then, all at once, the feverishness ceases, and there is rapidly an end to it. It will terminate, in fact, on the sixth day, instead of the eleventh.

*It appears sooner after Inoculation.*—It is found, also, that the disease appears much more quickly when it is communicated by inoculation, than when it is communicated naturally. The affection usually appears on the seventh, or at the latest upon the eighth day, when it is communicated by inoculation; whereas, when it occurs by infection, it is generally from the twelfth to the fourteenth day before it appears;—and consequently we may, by inoculation, anticipate infection. If a person has been exposed to the infection of small-pox, and has great chance of having a severe disease, it is right (if we do not vaccinate him) to inoculate him immediately; because we then produce the disease more quickly than it would otherwise occur. The artificial form gets the start of the natural; and the patient has the former, instead of the latter.

*The Quantity of Matter Influences its Severity.*—Dr. Fordyce also mentions, that the quantity of matter applied, greatly influences the severity of the disease. He says, that if we introduce only a small quantity of matter, a less severe disease is produced, than if a considerable quantity be employed. On this account, the quantity of matter should be as sparing as possible. It should only be just sufficient to produce the disease. In cow-pock, however, a different rule must be observed; because the object, in that case, is to have the affection as complete as possible; and therefore a considerable quantity of matter must be introduced. We must not be contented with making one insertion: but must make several.

*History of Inoculation.*—The fact of inoculation rendering the disease milder, appears to have been communicated to the Royal Society of Edinburgh in the eighteenth century; and the knowledge of it to have been brought to England from Constantinople. The knowledge of this fact is said to have existed in China, and Hindostan, for a great number of years. The Chinese were in the habit of placing the crusts taken from small-pox patients in the nose;—having frequently kept them in jars for some years previously. Sometimes they reduced the crusts to powder, and made the children snuff them up;—this was called “sowing the small-pox.” The Brahmins are in the habit of scratching the surface of the skin, and then binding upon the scratch a piece of cotton moistened with the pus. It is said that a particular caste has the charge of this practice. They, however, prepare the patients for this process by some months’ abstinence;—even from milk and butter; and this would be pretty low diet; for they have no animal meat at any time. This mode of inoculation appears to have been long practised in Persia, Armenia, Georgia, and Greece; but its origin is unknown. Some imagine that it arose in the deserts of Arabia; where there were no physicians or priests;—nothing but old women; and that the knowledge of the fact was acquired by the vulgar. However, the practice appears to have been very long known, among the peasants, in the provinces of Italy, in France, Germany, Sweden, Denmark, and even in Great Britain. In the north of Scotland, the people were in the habit of giving the children the disease, by putting them to bed with others labouring under the affection; or tying threads soaked with pus upon their wrists. But although it was known in this way, among the lower orders, before the enlightened part of the public were aware of it,—just as we shall see was the case with regard to cow-pock preventing small-pox,—the practice ostensibly came to us from Constantinople. Dr. Timoni wrote to Dr. Woodward on the subject, from Constantinople; and the letter was published in the “Philosophical Transactions” the year after. Pylarini, a physician, also wrote on the ‘Turkish practice; and sent his communi-

cation home in 1715; and this was likewise given to the public in the "Philosophical Transactions." Lady Mary Wortley Montague was at Constantinople with her husband, who had been appointed ambassador to the Ottoman court; and she there learned the practice; and, being a courageous woman, tried it (with success) on her own son. On her return to England, she had her daughter inoculated. Caroline, Princess of Wales, wished to have her children inoculated; but was desirous that the experiment should first be made on six felons in Newgate. She obtained the consent of George the First; and the operation was performed. Five of the felons did well; but the sixth did not take the disease;—having, in fact, had it previously. On account of being inoculated, they were all saved from hanging. Inoculation was now thought favourably of in England; and it appears that, in the first eight years, eight hundred and forty-five persons were inoculated; of whom only seventeen died. At Boston, only one out of forty-five died.

As this was a new practice, it excited opposition. Whether the practice was good or bad, its novelty was sufficient to account for this; and many clergymen and dissenting ministers raved against it from the pulpit, and called inoculation "the offspring of atheism." Those who performed it, were called "sorcerers;" and the whole thing was said to be "a diabolical invention of Satan." Others, however, were of a different opinion; and Bishop Maddox and Dr. Doddridge defended it; and, in doing so, employed Scriptural quotations. The devil can quote Scripture, to suit his own purposes; and therefore it was very fair for good men to quote Scripture too. However, the reasonable side of the question at last prevailed.

After a time, the practice was nearly relinquished throughout Europe;—just as we saw<sup>a</sup> was the case with regard to the use of Peruvian bark. After the practice of exhibiting bark had been approved, the good opinion formed of it was entirely lost; so that it became "a *drug*" in the market; and inoculation was almost disused in England, from 1730 to 1740; and in France it was absolutely forbidden. The truth was, however, that inoculation caused a great loss of life. It saved the lives of a great part of those who were inoculated; but it kept up the pestilence to such an extent, that far more caught it than otherwise would have done so; and it increased the general amount of the disease.

*Success of Inoculation.*—With regard to the success of the practice, I may remark, that those who were not medical men, were frequently the most successful. Some Carmelitical friars inoculated the Indians of South America, very successfully; and the most successful inoculators, in every part, were non-medical men. A planter, at St. Kitts, is said to have inoculated three hundred of his slaves himself; without having lost one. Medical men made a great preparation for inoculation, by purgatives, emetics, and various drugs; and employed all these things also in the course of the disease. They likewise confined their patients to bed, and kept them in a hot room, with a view to encourage perspiration. This practice aggravated the feverishness, and increased the mortality from the disease. Great fury prevailed against it; when, in 1754, the London College of Physicians published a declaration in its favour. Inoculation, however, met with but slender success, till the time of a person named Sutton. This quack used purgatives, and common-sense treatment, and succeeded wonderfully; so that he spread inoculation, more than the College of Physicians and all the doctors together. Sydenham practised free ventilation and refrigerants; but Sutton omitted the opiates which Sydenham was in the habit of giving, and gave calomel and tartar-emetic. Sutton also restored the Turkish practice of making only a slight scratch with a lancet. The practice, indeed, fell very much into the hands of quacks. Medical men ceased to have recourse to it; but quacks took it up, and endeavoured to "turn a penny" by it.

Such is the curious history of inoculation. Its efficacy was first doubted; the practice was afterwards approved; then violent disunion and party feeling were

<sup>a</sup> At Page 272.

excited; the most virulent abuse was poured forth; and the plan was dropped altogether. Then it was taken up by quacks; and quacks were frequently much more successful than the doctors; because they did not employ a number of medicines, which did harm. When inoculation was first practised, it is said that only one patient out of fifty died; but now, not above one in two hundred dies; and some have calculated it at not more than one in five hundred; whereas the mortality from natural small-pox was as much as one in six, even where medical aid was rendered; and where there was no medical assistance, the mortality was frightfully great. In fact, at one time, nearly all died where medical aid was not resorted to. The annual deaths from small-pox in England, during thirty years of the last century, were from thirty-four to thirty-six thousand. Before vaccination was practised, and after inoculation was established, one child in seven throughout Russia, is said to have died from small-pox; whereas Spain, which did not trouble herself about inoculation, suffered far less than any other country;—the disease having been kept up in others by inoculation.

*Diagnosis of Small-Pox.*—[Before the appearance of the eruption, the diagnosis of small-pox is always liable to uncertainty, even with every attention to the character of the prevailing epidemic; for the precursory symptoms are common to other diseases. The grounds on which we attempt, at this early period, to determine the nature of the approaching disorder are:—1. The suddenness of the attack. 2. The absence of previous ailment. 3. The exposure to variolous contagion. 4. The having previously undergone one or more of the exanthemata. The diseases with which, after the occurrence of febrile eruption, small-pox may be confounded, are measles, febrile lichen, varicella, and secondary syphilis.

1. The papulæ of true small-pox are firmer than those of measles. They feel granular, like hard bodies, under the finger. In measles, too, there is accompanying cough, and watering of the eyes. Further: forty-eight hours elapse, in small-pox, from rigor to eruption; seventy-two hours in measles. 2. Febrile lichen is the disease from which small-pox, at the onset of eruption, is with most difficulty distinguished. The aspect of eruption is in both cases nearly alike. The surest and safest grounds of diagnosis are based on the interval which has elapsed from rigor to eruption, and the seat and extent of eruption. In febrile lichen, twenty-four hours elapse from sickening to eruption; in small-pox, as we have said, forty-eight. Small-pox almost always appears first on the face; the eruption of lichen is equally developed, from the first, on the trunk and head. The diagnosis of small-pox and chicken-pox will be pointed out by and bye.<sup>a</sup> 4. There is a form of secondary syphilis, in which an eruption appears on the face and trunk, very similar to distinct small-pox. This eruption passes through the several grades of papula, vesicle, and pustule. It is preceded by a febrile attack of variable duration. This circumstance has, in many instances, given rise to the notion of small-pox occurring twice. A case of this kind fell under our own observation<sup>b</sup> very recently. The diagnosis is to be effected by accurate inquiry into the prior history of the case, and the further progress of the eruption. The pustular syphilitic eruption runs a tedious course, exceeding ten days; and the pustules are developed, not simultaneously, (as in small-pox,) but in successive crops.

*Prognosis.*—The danger, in small-pox, is dependent on a variety of circumstances; but chiefly on the following:—1. The quantity of the eruption. 2. The condition of the mucous membranes. 3. The state of the fluids. 4. The state of the nervous system. 5. The age of the patient. 6. His habit of body. 7. The circumstances in which he is placed, and the treatment adopted.

1. Distinct small-pox is a disease of little or no danger. Confluence is always unfavourable, especially on the face; nor is the nature of the danger always understood. A confluent case sometimes appears to progress favourably; when, unexpectedly, a convulsive fit occurs, and the patient is destroyed. The drain which confluence necessarily occasions in the system is sometimes the obvious cause of

<sup>a</sup> See Page 445.

<sup>b</sup> That of Dr. George Gregory.

danger. Nevertheless, if the pustules on the extremities acuminate well, and are surrounded by a crimson areola, a good ground of hope exists. If the vesicles on the trunk and extremities, on the other hand, be flat, with a clarety areola, while the eruption on the face is white and pasty, no reasonable hope of recovery can be entertained.

2. The condition of the mucous membranes, especially that of the larynx, is equally important with reference to prognosis. Hoarseness at an early period of the disease, is always unfavourable. A natural tone of voice, again, is a good omen; even though the eruption be full and confluent, with a disposition to cellular inflammation. The appearance of the mouth and throat will also serve as a useful guide to the probable state of the larynx and trachea.

3. The condition of the fluids is a circumstance by which the physician will, in a great degree, be guided in his prognosis. Every thing which indicates malignancy and putrescency is highly unfavourable. Petechiæ, menorrhagia, mucous hæmorrhages, and vesicles filled with a bloody ichor, are therefore among the worst signs that can occur. Recovery from the petechial small-pox has been recorded; but it is among the rarest events which the history of this disease presents.

4. A tranquil state of the brain and nervous system is particularly favourable; and is the circumstance to which the recovery of all severe confluent cases is mainly attributable. Quiet nights, composure of manner, a contented disposition, and confident hope of recovery, are good signs; restlessness (on the other hand), a continual moaning, despondency of mind, and a succession of sleepless nights, afford but little hope of recovery. Children who grind their teeth seldom do well.

5. Age is a point of great moment, in estimating the comparative degree of danger in confluent and semiconfluent cases: the extremes of life are those on which small-pox always falls the heaviest. Persons above forty years of age, seldom recover, even from semiconfluent small-pox; infants are in danger, even from a moderate quantity of eruption: in both, the process of cicatrization is attended with great exhaustion of nervous power; the result of which is, that some internal organ necessary to life (the larynx, brain, or lungs) takes on acute and rapidly destructive inflammation. The arteries here act without the due control of the nerves. The most favourable age for taking small-pox, is from the seventh to the fourteenth year; when the powers of life are in full vigour, without the risk of plethora.

6. The habit of body is, of course, also to be taken into account. Small-pox is always aggravated by its concurrence with a *plethoric* habit. Great constitutional debility is equally to be dreaded. In the strumous habit, the sequelæ of small-pox are peculiarly severe, and often bring life into danger after the crisis has been passed.

7. The probability of recovery must depend, lastly, upon the circumstances in which the patient is placed; on the possibility of applying remedial measures effectively; on the treatment which has been pursued in the early stages, and other contingencies which scarcely admit of enumeration. In hospitals, the danger of contracting fever and erysipelas, during the later stages, is never to be lost sight of. In private life, small rooms, superabundant bed-clothes, and ill-timed cordials, may aggravate or bring on local congestions and inflammations, from which the hospital patient is exempted. In certain seasons and states of the air, small-pox is more to be dreaded than at other times.

These principles of prognosis will lead naturally to the consideration of the average mortality in small-pox, the usual sources of death, and the morbid appearances.

*Mortality.*—The average mortality by small-pox is usually stated as one in four of those attacked, or twenty-five per cent. At the Small-Pox Hospital, the extremes have been fifteen per cent. and forty-two per cent. The average of twenty-five years prior to the introduction of vaccination, gave thirty-two per cent. The proportion which the mortality by small-pox bears to the total mortality in any town or district, has been a favourite subject of inquiry with all writers on medical

statistics. Prior to 1800,—that is, before the period when vaccination influenced the results,—the deaths by small-pox were to the total deaths, both in town and country, as sixteen to one hundred. It has been observed, by all writers, that in the unprotected the greatest mortality takes place in the early periods of human life. Dr. Haygarth computed that at Chester, in the latter part of the last century, one half of the deaths in children below ten years of age, was due to small-pox. The mortality is heaviest from the second to the fifth year. From the "First Report of the Registrar General of England," it appears that in 1837, there were only five diseases more fatal in England than small-pox; and that the deaths throughout England and Wales, by that disorder, amount now annually to about 12,000.

Small-pox may prove fatal at any period from the first invasion of fever to the fortieth day. Death may even take place prior to the development of eruption; but such cases are rare. In all countries it has been observed, that the eighth is the day of greatest danger, and the second week that which exhibits the greatest amount of mortality. The following table, extracted from the records of the Small-pox Hospital for 1828-9, showing the period of eruption at which 168 patients died, and the days on which the disease proved fatal, illustrates this; while it points out how little importance can be attached to the doctrine of critical days in small-pox.

Of 168 fatal cases of small-pox there died on the

First week.	Day.	Cases.	Second week.	Day.	Cases.	Third week.	Day.	Cases.	Fourth week and later.	Day.	Cases.
	3d	- 1		8th	- 27		15th	- 7		22d	- 3

\* Of these there died of fever and superadded erysipelas, 14.

† Of these there died of fever and superadded disease, 10.

The concluding table will complete this branch of the subject, by pointing out the comparative mortality of small-pox at different ages; distinguishing the vaccinated from the unvaccinated.”<sup>a</sup>

The immediate causes of death, in small-pox, are various;—as the preceding detail of symptoms will have shown; but it may be useful to exhibit them in a condensed form:—1. Prior to the maturation of the pustules, (that is, from the invasion of fever to the seventh day of eruption,) small-pox proves fatal by that general derangement of the system which occurs in *malignant fever*. Such a condition of the body is well designated by the term “*acute malignancy*.” 2. During the second week of eruption, the chief cause of death is to be found in affections of the larynx and trachea, and consequent suffocation. 3. During the third week (that is, during the stage of secondary fever) death may happen either by general excitement,—leading to effusion of the brain; or by supervening pleurisy, pneumonia, or laryngitis; or, lastly, by extensive sloughy or gangrenous destruction of the skin. 4. During the fourth week, and at still later periods of the disease, death may take place from mere exhaustion; or it may be the result of erysipelas, or of some other disease excited by the small-pox, or engendered by that constitutional debility which such a disorder in any of its severe forms so frequently leaves.”<sup>b</sup>

*Treatment*.—There is nothing peculiar in the treatment of this disease. It is only the treatment of any ordinary fever. The utmost cleanliness should be observed; the patient should have plenty of clean linen; and mild antiphlogistic diet will be proper;—at least in the first instance. There is no harm whatever in cold or tepid ablution; provided the body is hot. Some say that they have stopped the disease by affusion; but we may have recourse to tepid ablution, if there be any objection to cold; and, as the fœtor is very great, it would be well to wash the patient with a solution of the chlorides, and to use them freely around the bed. Now and then it may be proper to bleed. The head is sometimes so much affected that, in the case of adults, general bleeding may be premised; or, at any rate, the application of leeches to the temples. The pain in the loins, which characterizes the disease, generally goes off very soon; but the oppression of the head may require local bleeding; or, in adults, *general* bleeding. Usually the latter is not necessary; but every practitioner must judge of that for himself. Purgatives are proper; for the bowels should be kept freely open. By cleanliness, the employment of the chlorides, purging, bleeding (general or local), and low diet, the disease will be got through in the most favourable manner.

After a time, if the patient’s pulse become weak, or if the pustules be not well filled, and there be no violent local disease;—if, in short, there be any signs of debility, and of the disease assuming a typhoid type,—then wine and stimulants should be given. Sydenham was in the habit of giving opium at first; and I certainly think, in that respect, his practice was bad. In confluent small-pox, when

the patient is covered with pustules, so great a number of little abscesses must be considered equal to one large one. There is universal suppuration of the surface; and the patient requires to be supported;—just as he would in the case of a common abscess. It is frequently necessary, also, towards the close of the disease, to give wine, ammonia, and sulphate of quina; together with good nourishment. But there may be, on the other hand, such sharpness of the pulse, and such general irritation, that measures of this nature are improper; and we must be contented with giving the patient, perhaps, no more than milk or whey, and keep him cool. There is, as I have already said,<sup>a</sup> nothing peculiar in the case; it is only the treatment of fever.

Some have advised the letting-out of the matter from each pustule. It is an old practice; but it has lately been talked of again. This might be done with a needle; and it is said there is some utility in the practice. Any inflammation that may occur (whether in the head, eyes, bronchia, or intestines) requires to be attended to. We must constantly be on the look-out for these affections; but the treatment is certainly to be conducted altogether on general principles. We have only to remember that we are treating, not merely an *inflammatory*, but a *specific* disease;—a disease attended by suppuration on the surface. Fresh air, cleanliness, and the chlorides, are very proper;—just as in other cases.

[Mercurial plasters are said to have the power of preventing the maturation of the pustules, and have been lately much recommended. I tried this practice in the Philadelphia city hospital, and feel satisfied from the experiments there made,<sup>b</sup> that the mercurial plaster exerts a decided influence upon the pustules, preventing more or less their perfect maturation, and diminishing the concomitant inflammation, swelling and soreness. The subsequent process of desiccation, too, is less likely to be accompanied by the formation of thick scabs, and the resulting cicatrices less marked, than when the eruption is left to pursue its natural course. I did not find, however, that it prevented pitting altogether, but only that it lessened the liability to it. Independently, however, of its influence in this respect, the application of the mercurial plaster to the face, is valuable in some cases, with the view of moderating the inflammation, as the patient is thus relieved of considerable swelling and pain, as well as from the inconvenience arising from the formation of thick scabs. The strong mercurial ointment was used in some cases, whilst in others it was rubbed down with an equal bulk of lard. It was spread upon a piece of thick muslin shaped like a mask, and then carefully applied to the forehead and face. Its good effects are chiefly observable where the eruption has not advanced beyond the third or fourth day. T. S.]

## SECTION VI.—VACCINIA.

*Nature.*—The next disease which I shall describe, the cow-pock, was placed, by Drs. Willan and Bateman, in the order “vesiculæ;”<sup>c</sup> but although there are only vesicles at first, the contents become so turbid that, at last, there is genuine pus; and I think it is much more consistent altogether to put it in the same order with small-pox. Indeed the cow-pock (called “vaccinia,” from “vacca,” a cow) is believed, by many, to be nothing more than a modification of small-pox;—to be merely the small-pox, modified by passing through the cow. There can be no doubt that small-pox is an affection which cows, and perhaps other brutes, may have. Accounts have been published, in different journals, of experiments made with a view of ascertaining this point. Clothes have been taken from patients labouring under small-pox, and laid on cows; and they have had the disease called “cow-pock.” If the disease be really small-pox, modified, we then see no wonder in the circumstance that *cow-pock* generally affords an immunity from *small-pox*.

<sup>a</sup> See Page 437.

<sup>b</sup> American Journal of Medical Sciences, January, 1843.

<sup>c</sup> Order 5.

Cow-pock, however, is a far milder disease than small-pox; and is strictly contagious. It cannot be communicated by *infection*, as small-pox may; it is only communicated by palpable matter.

*Are Variola and Vaccinia Identical?*—[The answer to this interesting question, is to be found in the late very interesting researches of Mr. Ceeley, published in the last volume of the Transactions of the Provincial Medical and Surgical Association. In the report on this subject, we are informed that Mr. Ceeley—

“Resolved to attempt to ascertain whether he could, by inoculation, impregnate the cow with human small-pox. Twice he has succeeded in accomplishing this important object, after many previous fruitless trials. His experiments were conducted in the presence of five medical men and one veterinary surgeon. He produced five vesicles on the cows; from which source several hundred patients have been vaccinated, and have exhibited all the phenomena of vaccination, in the most perfect form and complete degree. There was no attendant eruption; nor any thing that could lead him to suspect, that he had not in this manner propagated the genuine ‘variola vaccinae.’ He kindly transmitted portions of this lymph to the President of the Section, who immediately committed it to the care of Mr. Coles and several other gentlemen; in whose hands it produced regular vesicles, which in every respect corresponded with those so beautifully delineated by Dr. Jenner, in his first publication.” This circumstance forcibly arrested the attention of every one who saw the vesicles; and that too, in several instances; though the source whence the lymph was derived was not known. The correctness of the vesicle formed by it, exhibits a marked contrast to that which we have seen produced by other virus now in use; and we fear that the local as well as general disturbance occasioned by the latter, so far from being a source of protection, will be found to be the reverse.

“On the first of February, 1839, he inoculated with small-pox matter (‘variola discreta’) of the seventh or eighth day, three young heifers; a fourth was, at the same time, vaccinated. The reporters limit their account of what happened to the first.

“Mr. Ceeley made seven punctures, and introduced fourteen points near the left *labium pudendi*; and, on the same day, inserted two setons with matter from the same subject. On the ninth day after this process, he vaccinated the same animal on the right *labium pudendi*, with fifth, sixth, and seventh day’s lymph from a child, in seven punctures with fourteen points; and below the pudendum, in four punctures with eight points. On the tenth day after the insertion of the variolous matter, one of the punctures, near the posterior margin of the left *labium pudendi*, had assumed the form of the natural vaccine vesicle. By gently removing the central irregular crust, and carefully puncturing the cuticle, he was able, in the course of an hour, to charge thirty-eight points with lymph, and on the same and subsequent days to use part of it on children and adults. On the thirteenth day the small-pox vesicle was more inflamed and florid; this was the fifth day after the insertion of vaccine lymph, at which time all the eleven punctures were converted into effectual vesicles; from these he took fine clear lymph, and used it on children and adults. Both the variolous and vaccine vesicles subsequently ran nearly a parallel course; so that, on the twenty-sixth day of the former, and on the seventeenth day of the latter, the scars of both appeared perfectly similar.

“To obviate objections which might arise from the insertion of the vaccine lymph on the ninth day after the inoculation with the variolous matter, Mr. Ceeley re-inoculated a sturk on the fifteenth of February with small-pox matter, of the seventh or eighth day, on the *labium pudendi*. He made eight punctures; which were deluged with the variolous fluid from capillary tubes. On the fifth day,

“An Inquiry into the Causes and Effects of the Variola Vaccinae;—a Disease discovered in some of the Western Counties of England, particularly Gloucestershire; and known by the name of the ‘Cow-pox.’ By Edward Jenner, M. D.” See, also, his “Further Observations on the Variola Vaccinae;” and “Continuation of Facts and Observations relative to the Variola Vaccinae, or Cow-pox.”

the four upper punctures were enlarged and elevated; the other four were less so. On the sixth day all presented the appearance of the vaccine vesicle. From one of them he took lymph with difficulty, and scantily charged thirty-nine points. On the eighth day, he again took lymph from the vesicle opened on the sixth. On the ninth day, the vesicles were enlarging; and he again opened carefully the first vesicle and charged twenty points. On the tenth day, the four lower vesicles were increasing; and from them he charged twenty-seven points. After this time the brown crusts appeared, and the disease gradually declined. This animal was subsequently inoculated, both with variolous and vaccine matter; but no result followed.

"The practice of inoculating the cow with vaccine virus taken from man, was very early attempted. It is not to be overlooked, that the difficulty of accomplishing this is almost as great as that of inoculating the animal with small-pox. It succeeded, however, in the hands of Dr. Waterhouse; who, in 1801, impregnated one of his cows; and obtained from her a 'crop of matter on the ninth day, which produced the disease in the human subject to perfection.' Mr. Fox, of Cerne Abbas,—who has paid great attention to this subject, and seen the disease, as well among the cattle as on the hands of the milkers,—has also successfully vaccinated the cow.

"The same experiments have been performed at Passy, in the neighbourhood of Paris. The lymph found there in 1836, among the cows, has been recently again passed through the animal; and this is called 'retro-inoculation.' Mr. Ceeley, too, has often been enabled to communicate the vaccine disease from man to the cow. He has observed, that good human lymph, when transmitted in this manner, loses some portion of its activity. It rises late, and produces smaller vesicles; but ultimately, *after successive inoculations on man*, it resumes its activity.

"The reporters rightly designate this a triumphant conclusion of an investigation of more than fifty years' duration; and the best monument to the sagacity of Jenner. They deduce from what has been done the following aphorisms; to which they entreat the attention not only of the profession, but of the public:—

"1. Cattle, in many ages and different countries, have been afflicted with small-pox.

"2. This disease among the inferior animals has simultaneously existed with the small-pox in man, and pursued its victims through every quarter of the globe; and it exists at this time in Asia, in a fatal and pestilential form.

"3. It appeared among the cattle in England in the year 1745, and again in 1770, and continued its ravages up to the year 1780; and the local remains of this epizootic still occasionally show themselves, with considerable severity.

"4. The casual transmission of this disease to the milkers in the dairies of Gloucestershire, and their subsequent immunity from human small-pox, first led Dr. Jenner to the investigation of this singular affection, and ultimately to establish it as a substitute for the more pestilential and fatal form of the disease.

"5. When the disease appears among the inferior animals in a malignant form, it produces, by inoculation, a disease of similar severity in man.

"6. As man has received this affection from the cow, so likewise has the cow received it from man.

"7. The direct inoculation of the cow with human small-pox, has produced a mild and mitigated disease; and such disease, reproduced by inoculation on man, accords entirely in its character, in its progress, and in its protecting influence, with the 'variola vaccina,' as described by Dr. Jenner;<sup>a</sup>—thus irresistibly proving his fundamental proposition, that cow-pox and small-pox are not *bonâ fide* dissimilar, but identical; and that the vaccine disease is not the preventive of small-pox, but the small-pox itself;—the virulent and contagious disease being a malignant variety."<sup>b</sup>]

<sup>a</sup> See Page 439.

<sup>b</sup> "Medico-Chirurgical Review;" October, 1840; Page 399. This extract has come to us through the medium of Braithwaite's "Retrospect of Practical Medicine and Surgery, for the year 1841." (Pages 259 to 262.) As a work of reference and record, this is a very

*Phenomena.*—The disease, given artificially, begins a few days after the poisonous matter has been inserted into the body. By a slight scratch, or by a wound of any description, a small transparent pearl-coloured vesicle is formed, with a circular or somewhat oval base. The upper surface is more elevated at the margin than at the centre, till the end of the eighth day;—the margin itself being red, turgid, shining, and roundish; so that it often extends a little over the line of the base. The vesicle contains clear lymph, in little cells that communicate with each other. About the eighth or ninth day, it is surrounded by an areola, varying in diameter (in different cases) from a quarter of an inch to two inches; and is usually attended with considerable swelling, and hardness of the adjoining cellular membrane. The areola declines from the twelfth day. The surface of the vesicle then becomes brown in the centre; and the fluid concretes into a hard round scab. The colour afterwards becomes black; and so it may remain for two or three weeks. It is important to remember, that there is left a permanent cicatrix, about four or five lines in diameter; the surface of which is marked by pits, denoting the number of cells of which the vesicle has been composed.

The vesicle is formed about the *sixth* day after the insertion of the virus. About the *seventh* or *eighth* day, there is an inflamed areola;—a swelling and hardness; and it is on the *eleventh* day that all the symptoms decline. The vesicle then becomes muddy, and darker. If there be any pyrexia of the system, it occurs about the *eighth* or *ninth* day. Now and then (and I have seen such a case myself) the disease has not appeared for two or three weeks after vaccination; and then suddenly the disease has begun, inflammation has taken place, and the affection has gone through its regular process.

*Indications of Perfect Vaccination.*—If there be a violent degree of inflammation, or if the disease vanishes too rapidly, or if there be any variation from its proper course, we must not imagine that any security from the small-pox is afforded. If, on the one hand, there be too little inflammation,—so that the affection soon subsides, and no genuine vesicle is formed; or if, on the other hand, there is too violent an inflammation; then, in either case, we may doubt whether the disease will be of any use. Nay, more: if the cicatrix, after the disease has appeared to go through its stages properly, is not of the description which I have now mentioned;—if there be not a permanent cicatrix, about five lines in diameter (a little depression, with very minute indentations,) we may then suspect that the disease has not been perfect. In the case of all contagious diseases, we may have a disease of the greatest mildness, or the greatest severity. A contagious disease will not only vary as to the time at which it appears after the virus has been applied, but it will vary as to the time at which it goes through its course;\* and it will vary as to its degree;—so that I am satisfied that the plague will sometimes occur with only a slight indisposition; and we continually see gonorrhœa so mild, as to last only twenty-four hours; whereas, in other cases, it will be so severe as to last some weeks. Now this general fact is strikingly shown in cow-pock. It continually dies away, from the disease not being fully formed; and, on the other hand, it sometimes is so very violent, that the whole course of the affection is disturbed. Nothing should occur for twenty-four, or perhaps forty-eight hours; and then there should be a little irritation. A vesicle ought to be gradually formed; on the seventh or eighth day there should be an areola, and all the symptoms should decline on the eleventh day. When it is all over, a dark and hard scab ought to be seen, for two or perhaps three weeks; and then a permanent cicatrix should be left; with little indentations, arising from the cells of which the pustule has been composed.

*Small-pox Modified by Vaccination.*—This disease, in the greater number of cases, gives immunity from the small-pox; and where it fails (which it frequently does) the small-pox is, in the greater number of instances, milder than it otherwise would have been. In general, when that disease occurs after cow-pock, it suddenly

useful publication; since it gathers into a small compass the most valuable medical communications, scattered through the different periodicals, in the course of the year.

\* See Page 311.

stops; it is ushered in by great pyrexia; and then, about the sixth day, it suddenly declines.

I mentioned<sup>a</sup> that the effect of inoculation for small-pox, is not of this description;—that it causes the disease to be produced with a smaller number of pustules; whereas vaccination does not lessen the number of pustules, but shortens the course of the disease; so that, about the sixth day, all the violence generally ceases. This, however, is not a universal occurrence; because some patients die of the small-pox, after they have had the cow-pock. At first, it was imagined that cow-pock was a *certain preventive* of the small-pox. That, however, was a hasty conclusion. Because it prevented the disease for a certain time, and in the majority of cases, that afforded no solid basis from which to infer, that it would prevent it in *all* cases, and for the rest of life. Further experience was necessary, before such a conclusion could with propriety be drawn. But we may now safely assert, that a great number of persons who are vaccinated escape the small-pox; and where persons do *not* escape, the greater number of them have the disease *very mildly*. I believe the whole of the matter comes to that.

*Circumstances Influencing the Protective Power of Cow-Pox.*—[Among the circumstances that materially influence the protecting power of cow-pox, is time. In the early periods of vaccination (1800 to 1805,) the practice of inoculating after cow-pox,—so as to test its prophylactic power,—was carried to a great extent; and many thousands were exposed to the variolous effluvia, with impunity. Since the year 1808, these experimental testings have almost entirely ceased; and, consequently, we know very little concerning the effect of inoculation at long intervals from the date of vaccination. But it is a matter of general notoriety, that small-pox taken casually after vaccination is very rare under the age of eight years. The protective power may be considered as nearly complete for that period. About the ninth or tenth year of life, small-pox after vaccination begins to be met with. It increases in frequency at the period of puberty, and is still more common between the ages of 18 and 25. With these facts before us, it is impossible to conceal the apparent conclusion, that time lessens the power of resistance to the variolous germ.

The influence exerted by an atmospheric constitution over the power of variolous resistance, opens a wide but hitherto neglected field of inquiry. Having now witnessed in London two severe epidemic visitations of small-pox, we<sup>b</sup> have no hesitation in stating, that such influence is undoubted. The fact does not, from its very nature, admit of direct proof; but the number of persons attacked during epidemic seasons, after having successfully resisted small-pox contagion *communibus annis*, offers an argument in favour of the position, which to our minds is irresistible.

We<sup>b</sup> come now to apply these views of vaccine pathology to the examination of the two practical measures suggested, of late years, to remedy the acknowledged defects of vaccine influence. The first of these is recurrence to the cow, for supplies of primary lymph. The second is revaccination, at distant intervals from the date of the primary process.

1. *Recurrence to the Cow for Primary Lymph.*—The impression that vaccine virus decays in power in proportion to the number of times that it makes the circuit of the human body, has long prevailed, and is steadily gaining ground. In all parts of the Continent, and in England, it has led to frequent trials of lymph recently obtained from the cow.

Persons vaccinated by Dr. Jenner himself, in the very infancy of the practice, before such deterioration could possibly have taken place, have undergone small-pox in after-life. Such occurrences are now more common than formerly; but much may be attributed to the extension of the practice of vaccination. The Royal Jennerian Institution of London employs, now, the same lymph which has been in use since the year 1806, when the Institution was founded. According to this authority, lymph recently obtained from the cow, does not generate a vesicle in

<sup>a</sup> See Page 432.

<sup>b</sup> Dr. George Gregory.

any way superior to that produced by the old lymph. ("Report of the Royal Jennerian Institution," for 1836.) The same result was obtained in Italy, in 1829; when the alarm of epidemic small-pox induced the Piedmontese physicians to try a variety of new stocks of lymph. We are informed by Dr. Griva ("Epidemia Vainolosa del Torino," 1829), Chief of the Vaccine Establishment at Turin, that "no perceptible difference was to be traced between the aspect and progress of the old and the new, the primitive and the long humanized, virus." In Germany, the plan of recurrence to the cow has been largely tried of late years. In Wirtemberg alone, between 1831 and 1836, forty varieties of primitive lymph were successfully employed. The notion of superior efficacy attaching to the new lymph was, however, not generally entertained. (Heim's "Historische Kritische Darstellung der Pockensuchen.") On the other hand, we are bound to acknowledge, that the Small-pox Hospital of London, changed its old stock of lymph for more recent matter in 1837; and that a marked improvement was perceived in the resulting vesicles. The local inflammation was more severe; the constitutional symptoms were more violent; the virus was more energetic; the most minute incision took effect; and the lymph given out on the ninth and tenth day was still in an active state. The National Vaccine Establishment has also, on several occasions, varied its stock of lymph with advantage. In France, a new variety of vaccine lymph, obtained from the dairies of Passy, near Paris, and called "*Passy* lymph," was brought into use in 1836: and is considered by many as superior to the old stock. In 1838, Mr. Estlin, of Bristol, opened a new source of lymph from a dairy in that neighbourhood. It has been found very energetic: and is now employed in many parts of England, in preference to the lymph of the National Vaccine Establishment.

2. *Revaccination.*—By many of the physicians of Germany, this measure is extolled as scarcely less important in its effects, nor less widely applicable, than vaccination itself. The authorities in Paris, on the other hand, have reported to the French government against the necessity of revaccination; and there is really some difficulty in deciding on the actual merits of the plan. The Germans aver that few, if any, of the recently revaccinated have fallen under the influence of small-pox; but the time which has elapsed since the general adoption of the measure, detracts from the value of such a statement. The practice may be recommended for its safety, even if it be much less serviceable than the Germans contend for. We have sufficient facts before us to state, with confidence, that it need never be recommended prior to the tenth year of life; and that the year best fitted for it is from the period of puberty to that of confirmed manhood.<sup>a</sup>]

*Mode of Operating.*—This disease produces only a single vesicle or pustule. It does not produce a number all over the body; as small-pox, and other pustular diseases, do. As it is very desirable that the disease should be fully formed, and the constitution thoroughly affected by it, it is the practice to make several insertions of the matter; perhaps two in each arm. The arm is as convenient a place as can be chosen; and it is usual to make two wounds in it. The lancet should be held so that the matter may gravitate into the wound. There is no treatment required in this affection, unless we think it advisable to give the child a mild aperient.

*History of Vaccination.*—As to our knowledge of the effect of this disease, in preventing the common form of small-pox, I may mention, in a few words, that we are indebted for the publication of the fact to Dr. Jenner. In 1768, when he was an apprentice, he learned by report that the cow-pock, on the hands of milkers, prevented them from having the small-pox; and he very frequently, at his master's, had to dress the hands of such persons. From his inquiries, he satisfied himself that the ulcers he dressed, were derived from the teats of cows. He learned, too, that it was very well known among the peasants, in that part of the country, that persons who had these sores upon their hands, could never be made to take small-pox by inoculation. In the further prosecution of his studies, he came up to

<sup>a</sup> "Library of Medicine;" Volume I; Pages 325 and 326.

London; and having returned to the country, and settled there as a surgeon, he commenced a series of inquiries into this matter. He found a very considerable number of persons insusceptible of the small-pox; and, in all these cases, he was assured that the persons had had the cow-pock. The oldest farmers, however, said that the idea was not known in their younger days. Notwithstanding this insusceptibility which he found among so many persons, he met with exceptions; and he found some who had had those sores, and yet afterwards had the small-pox. Some medical men, of whom he made inquiries, believed the fact; and others disbelieved it. He found the difficulty cleared up, in a great measure, by ascertaining that there were several sorts of sores, arising from cows' teats, which were communicated to those who milked them; but that there was only one which was the genuine cow-pock. He likewise had to encounter another obstacle. From the influence of external circumstances, the pock among the cows ceased; and he was unable to make any experiments on the subject. I mentioned,<sup>a</sup> when speaking of contagious diseases in general, that affections, respecting the contagion of which there can be no doubt, will sometimes cease, and sometimes cannot be made to spread;—merely (as it would appear) from certain external circumstances. Now cow-pock—which is only *contagious*, not *infectious*—is said to have ceased for a time; so that it was impossible for Dr. Jenner to get matter with which to make experiments.<sup>a</sup> However, in 1796, the cow-pock broke out in a dairy-maid, whose finger had been scratched. From this finger he vaccinated a boy; and regular cow-pock was produced. He repeated the experiment on another;—taking the virus from the human subject; and he then likewise produced the disease. He mentioned the facts to several of his medical friends; and prepared a document to lay before the Royal Society; but he was advised, in kindness and true friendship, not to expose himself by communicating any such nonsense, merely because it was new. However, he persevered. He did communicate his knowledge to others; and just the same fury was excited among medical men, that had been excited formerly, when inoculation was first made known to them.<sup>b</sup> It was said that it was taking the power out of God's hand; that God gave us the small-pox; and that it was impious to interrupt it by the cow-pock. When I was a boy, I heard people say that it was an irreligious practice; for it was taking the power out of God's hand;—forgetting that it is merely *using* that power which God has given to us. Sermons were preached for it, and against it; and hand-bills were stuck about the streets. I recollect seeing it stated, in a hand-bill, that a person who was inoculated for the cow-pock, had horns growing in consequence of it. Many were said to have died of mortification, produced by this practice. One of the surgeons at St. Thomas's Hospital,<sup>c</sup>—there being no clinical lectures then,—used to give gratuitous lectures against the cow-pock; in which he advised the students not to resort to such a practice. He was interred in London; and, by his direction, a tablet was erected to his memory; on which was inscribed the fact, that he was all his life strongly opposed to *cow-pocking*. His rancour did not cease even with his death. It appears that a great want of candour and of principle was manifested; and that an account was forged, setting forth a number of deaths as having arisen from the disease. After a time, however, all this ceased; and now, I need not say, it is a regularly established practice; although it certainly does not deserve such encomiums as Dr. Jenner supposed it did. It is not an absolute preventive of the disease; but it does prevent it in a large number of cases; and where it does not, it generally makes it much milder. I will not take up more time with its details; because Mr. Moore's "*History and Practice of Vaccination*"<sup>d</sup> (which is almost as amusing as a novel) contains every thing that can be said respecting it.

<sup>a</sup> See Page 309.

<sup>c</sup> Mr. Birch.

<sup>b</sup> See Page 433.

<sup>d</sup> See Note (b) to Page 426.

## SECTION VII.—VARICELLA.

There is another disease, very much allied to all these; and called "the *little* small-pox," "varicella," (the diminutive of "*variola*,") or (in common language) "the *chicken-pox*," or "*swine-pox*." In general, it requires no treatment; any more than *cow-pox*. It is only important to know that there is such a disease; because people frequently think that their children are going to have the small-pox, when they are not.<sup>a</sup>

*Diagnosis*.—The affection begins as a vesicular disease; but there are generally some pustules. There are, however, fewer pustules than in small-pox; and, for the most part, they did not amount to more than two hundred. They go through their course, too, with far greater rapidity than small-pox; and there is very little irritation of the system; frequently none at all. It is sometimes a difficult matter to distinguish between it and small-pox; but when we consider that the disease has far fewer pustules, that it generally runs through its course with great rapidity, and with scarcely any disturbance of the system, there is no great difficulty in making the diagnosis; more especially if we know that the child has had the small-pox before.<sup>b</sup> It is said that, in chicken-pox, there is always cough; that a case never occurred, without being attended by some degree of cough.

*Symptoms*.—It is a contagious affection; and there is a little feverishness before the disease takes place; but in about six days the whole is over. I believe there is never any internal affection, of any consequence, when this disease exists. In very rare cases, there are violent pyrexia, headache, delirium, and even convulsions; but they are all transient. There is no severe affection of the larynx, of the bronchia, or of the intestines; as there is in many other cutaneous diseases.

*Identity with Small-Pox*.—Some have imagined that this disease is only a modification of small-pox;—that it is only a milder form of the disease called "*modified* small-pox;" but I will not give any opinion on the subject; because I do not think that we have sufficient observations, on these various diseases, to enable us to speak with any degree of certainty. After this disease, just as after small-pox,<sup>c</sup> I have frequently seen ecthyma and rupia take place; and sometimes, as in small-pox,<sup>d</sup> there have been scars. I had the small-pox myself, and was not pitted at all; but the chicken-pox came afterwards, and left several pits;—so that the disease occasionally produces pitting, here and there;—the same as small-pox.

[Dr. Thomson maintains, that varicella is nothing more than modified small-pox; and supports this opinion by the following arguments:—1. Persons placed in contact with patients affected with chicken-pox, have contracted variola; and the contagion of the latter affection has given rise to varicella. 2. Wherever small-pox is epidemic, varicella is also observed. 3. Chicken-pox is never developed, except in persons whose constitutions have undergone some modification from vaccination, or a previous attack of small-pox. This opinion of Dr. Thomson, however, is far from being generally adopted, even by those who coincide with him entirely respecting the varioloid nature of the vesicular eruptions observed in small-pox epidemics. The following are the arguments they use:—1. The true vesicular varicella cannot be transmitted by inoculation; and never, in any circumstances, generates small-pox. 2. Those persons who regard varicella as contagious, have confounded it with the modified small-pox. 3. Chicken-pox may

<sup>a</sup> The best description of this disease, is contained in Dr. Heberden's "Commentaries," Chapter 96; and is well worth reading. The appellation he gives it, is "*variolaë pusillæ*;" and he states his belief, that the "*chicken-pox*" and "*swine-pox*" differ only in name.

<sup>b</sup> "In the true chicken-pox, the vesicles have not that regular organization, which we have described as belonging to, and actually essential to the existence of variola, even in its mildest aspect. (See page 427.) The vesicles of chicken-pox have neither a hard papuliform base, nor cells, nor central depression. They are mere elevations of cuticle, of irregular and undetermined shape." ("Cyclopædia of Practical Medicine," Volume 4; Page 431.) This eruption is well represented in Willan's work on Vaccine Inoculation.

<sup>c</sup> See Page 429.

<sup>d</sup> See Page 427.

occur in persons who may have not been vaccinated, and who have never had small-pox; in whom, therefore, it cannot be regarded as the modified disease. 4. Vaccination practised shortly after the subsidence of varicella, observes its regular course; which is never the case after variola. 5. The course of varicella is always the same, whether it shows itself after vaccination or after small-pox. 6. Both these affections may prevail as epidemics, independently of each other. We have known it prevail epidemically, to a remarkable degree, in localities where not a single case of small-pox was observed.

*Varieties.*—There are two varieties of varicella. In the first the vesicles are small, but slightly elevated, and contain a colourless fluid. It is to this form that the name “chicken-pox” is more properly applicable. In the other, the vesicles are large, globular, soft, and broader in the circumference than at the base. The contained fluid is limpid at first; but afterwards has a milky appearance (“*swine-pox*”).

*Chicken-pox.*—In the varicella with small vesicles (“*varicella lenticularis*” of Willan; “*chicken-pox*”), small, pointed, transparent, red vesicles appear suddenly on the first day, and increase in size for two or three following days. On the second or third day, the fluid has a milky appearance, and the vesicles become shrivelled; on the fourth day they are surrounded by red areolæ. Desiccation begins on the fifth day; and on the sixth the vesicles are changed into small brownish scales. These desiccate from the circumference towards the centre, and fall off about the ninth or tenth day. As the vesicles appear in succession for two or three days, the different stages of the eruption may be seen at once in the same individual; so that the duration of the complaint may be prolonged into the eleventh or twelfth day.

*Swine-pox.*—Varicella with globular vesicles (the “*varicella globata*,” or “*swine-pox*”) is preceded by the same symptoms, and developed in a similar manner. The red points are quickly replaced by large round vesicles, containing a transparent fluid, which becomes opaque on the second day of the eruption. The vesicles have then reached their greatest size; they are soft and flabby; their colour is of a pearly white; and their circumference is larger than their base, which is surrounded by an inflammatory areola.

About the second day, the vesicles become faded and wrinkled; their fluid is thickened, and converted into a yellow colour. As the itching is generally very considerable, it often happens that the vesicles are torn, especially in children; by which the inflammation is increased, and yellow pus (of more or less thickness) formed. This accident most frequently occurs on the face; where the succeeding scabs may remain a considerable time, and produce permanent scars or pitting. This occurrence may also take place in the preceding variety.

The vesicular are succeeded, about the fourth day, by lamellated scales of a brown colour. These also desiccate from the circumference towards the centre, and fall off about four or five days after;—leaving little red marks, which gradually disappear.\*]

### *c. Tubercular Eruptions.*

## SECTION VIII.—ACNE.

Those eruptions of which I next proceed to speak, are not placed by Bateman with *pustular*, but with *tubercular* affections; because there is a considerable hardness of the skin. The fact is, however, that suppuration generally takes place in these affections, if they last long; and I therefore prefer arranging them, with Rayer, as *pustular* diseases. There is only this difference in them;—that there are *chronic* pustules, instead of *acute* ones,—they are *blind*, as people commonly say.

\* “Library of Medicine;” Volume 1; Pages 389 and 390.

*Nature.*—The first of these to which I will allude, is called (by Willan and Bateman) “acne;”<sup>a</sup> and (by Rayer) “couperose.” It is exceedingly common, and not at all contagious; nor is there the least harm in it. It occurs particularly in young men and women,—especially the former; and prevents them from being very handsome, about the period when they wish to “look their best.” Sometimes the face will continue to be affected with this disease for four or five years.

*Acne Indurata and Simplex.*—In the ordinary form it is called “acne simplex;” and is described, by Bateman, as an eruption of small pimples, not very numerous, and without much inflammation;—the surface between the pimples being perfectly healthy; with the exception of a little roughness of the face. Sometimes there is a very great hardness; and it is thence called “acne indurata.”

*Acne Punctata.*—Now and then it causes the sebaceous follicles to be large and distinct, and marked with a black speck on the top; and then it is called “acne punctata.” By squeezing them, we force out what is called a “maggot;” but it is only the contents of the sebaceous follicles; and by repeated squeezing, we may force out this secretion, as long as the follicles will supply it. It will take place in the neck; but the face is its usual seat. Many people have a little of this affection; but some have it very severely. There is no occasion to remember the particular names. Sometimes there are black specks; and sometimes there is a good deal of redness around them.

*Acne Rosacea.*—Now and then, it occurs with considerable surrounding redness and prominence of the skin; so that we may discover each particular vessel; and from its redness it is then called “acne rosacea.” We see this in middle-aged and elderly persons; and in this form the “maggots” lie in a bed of roses. This is a very permanent complaint. I do not know that it is often got rid of; but, luckily, it does not occur till late in life; and it is taken for granted to be an indication of being devoted to the bottle. Every person, who has such a nose as is represented in Willan’s sixty-fourth plate, is set down for a tippler.

*Suppurating Stage.*—Each of these hard inflamed pimples of the skin, may suppurate. Some will *subside* after a time, but a great many *suppurate*; and if they do not, it is an instance of termination by resolution; and we ought not the less to call it “a pustular disease;” because, if it pursue its course,—if it be not arrested by some cause or other, it goes on to that end. If it is not resolved, supuration is the termination of it.

*Treatment.*—There can be no doubt that, when these pimples are small, it is much the best practice to squeeze them, and empty the contents. If this be done, the tubercle will for the most part subside; and of course, if they suppurate, the sooner the matter is let out the better. I am not aware that internal medicine has any effect on the disease; but I have seen great benefit arise from the application of stimulants; and one of the best is the ointment of the nitrate of quicksilver,<sup>b</sup> rubbed well upon the part. This stimulates the disease; which seems to be one of inaction. Of course, if it stimulate too much, cold applications should be employed, and the irritation diminished. Sometimes this ointment is too strong; and then it is necessary to dilute it with simple spermaceti-ointment, or with zinc-ointment.

Some people give sarsaparilla, and nitric acid, in these complaints; but I do not know that they do any good; nor do I know that “Plummer’s pill”<sup>c</sup> is serviceable; but I think I have seen benefit from tar-water. The best local applications, are the stimulating substances that I have now mentioned. I have seen the face swollen all over, when they have been employed; and of course, if any very great inflammation come on, that must be treated in the ordinary way.

<sup>a</sup> From *anqui*, pimples on the face.

<sup>b</sup> “Unguentum Hydrargyri Nitratis.”

<sup>c</sup> “Pilule Hydrargyri Chloridi Compositæ.”

## SECTION IX.—SYCOSIS.

This is another disease which occurs in the face; but chiefly upon those parts which are covered with hair. It takes place, particularly, in the beard of men; and, from its appearance when ulcerated, it is called *sycosis*.<sup>a</sup> When it occurs on the chin, it is called "*sycosis menti*."<sup>b</sup> If it occur about the margin of the hairy scalp, it is called "*sycosis capillitii*."<sup>c</sup> There is, however, no occasion to make a variety, because it occurs in these different situations. We might as well make varieties of rheumatism, according as it attacks the *shoulders*, or the *knees*.

*Characters*.—The tubercles, in this disease, are not so hard as in *acne*. They continue for a length of time, and are more inclined to suppurate. It makes shaving an unpleasant operation; notwithstanding that we have a good razor, a good strop, good soap, and warm water. These affections are merely slow chronic pustules; and the complaint is exceedingly obstinate.

*Treatment*.—I have not seen the disease much relieved by bleeding, either general or local; or by the exhibition of mercury; but, of course, there are cases where antiphlogistic measures are proper. I have seen it subside from the administration of iron; but, for the most part, applications of all kinds fail. Stimulants may be applied; but, after a time, they do no good. Or we may employ cold soothing applications; but, after a time they also lose their effect.

It is absurd to call these "*tubercles*;" for there is simply *inflammation*. There is no tubercle;—no organic change in the skin. The gentleman represented in Plate 65 (of Willan), must have regretted having a beard. *Acne* is a disease of the follicles: and is frequently attended by extreme hardness; whereas *sycosis* is not so hard. I really do not know what to recommend in the disease. Every one must be left to his own judgment. I have been tired out and out by the treatment. Of course, as this is a disease which occurs in the beard, women are exempt from it; unless their ovaries begin to dry up, and they acquire the character of men; but it does not occur where there is no hair. Both these diseases are confined to the head;—*acne* to the face at large; and *sycosis* to those situations where there is hair. Rayer gives a drawing of both these affections.

## d. Boils.

*Classification*.—The other pustular diseases which I shall describe, are not treated of by Willan and Bateman; but they are all, or nearly all, spoken of by Rayer. One, however,—to which I will now direct attention,—is not spoken of even by him. Rayer makes a distinct class of those diseases which are disposed to gangrene. Now and then plague is attended by pustules on the skin (*large ones, indeed*;—such as are commonly called "*boils*"); and there is a great tendency to gangrene. The same occurrence takes place in the disease called "*pustule maligne*,"—"malignant pustule;" which is generally communicated from brutes. He makes a separate class of these; but they are merely suppurations; and therefore, I think, they ought to be classed with pustular diseases. However, if the suppuration be very considerable (forming not merely *pustules*, but a very extensive suppuration), it may only lead to confusion to speak of them in that way; and it is to be remembered that they are not merely pustules; but that the *cellular membrane* is chiefly implicated, and the *skin* only *secondarily*. Still, however, as the disease occurs on the surface of the body, it is well to consider it as an affection of the skin.

*Sties, Boils, and Carbuncles*.—The most simple affection of this description, is a sty of the eye. A more severe one is a boil in which there is a disposition to gangrene; and another is a carbuncle, in which there is a *strong* disposition to

<sup>a</sup> From *σύναν*, a fig.

<sup>c</sup> From "*capillitium*," the scalp.

<sup>b</sup> From "*mentum*," the chin.

gangrene. These three diseases (not one of which is mentioned by Willan and Bateman) Rayer puts together; and calls them "*boily* diseases;"—diseases characterized by *boils*. A carbuncle is only a large boil; but it is of such an extent, that surgical aid is necessary to let the matter out. He makes another kind, differing only in having a tendency to gangrene. Of this kind are "malignant pustules" (which he includes among the "inflammations gangreneuses"), and the plague. To these may be added another;—"the glanders" of horses;—a disease which may be communicated to the human subject.

*Malignant Pustule, Plague, and Glanders.*—With respect to sties, boils, and carbuncles, I shall say nothing; because they are spoken of in treatises on surgery. Those of which I shall speak are "malignant pustules," "the plague," and "glanders." The plague, indeed, is not confined to the surface; but neither are many other affections called "skin-diseases" (small-pox, for example). It is a general affection of the system; and involves the skin among other parts. The characteristic of these suppurations, is a disposition to gangrene. In respect to all these diseases, whether *small* ones (such as sties and boils), or *great* ones (such as malignant pustules and the plague), they bear the same relation to porrigo and bullæ, that the latter do to the small vesicles of herpes. I said,<sup>a</sup> that I thought it wrong to separate them; and so, with respect to these, I think it a pity to make different classes merely on account of their size. Because small-pox and porrigo have *small* suppurations, and plague or carbuncle is characterized by a suppuration of *greater* extent, it is no ground for constituting a different class of diseases. They are merely *pustular* diseases, with suppurations on a *large scale*.

## SECTION X.—THE PLAGUE.

The plague is very similar to typhus and continued fever; but it so affects the surface of the body, that I have thought it well to speak of it among diseases of the skin, as Rayer has done.

*Symptoms.*—Like many other diseases of the skin, it is an acute fever; attended by headache, delirium, and a burning sensation at the epigastrium. Perhaps there may be great strength of body at first;—the person may be of a full phlogistic diathesis; but great debility soon comes on; and very often there is debility from the first. Glandular swellings speedily appear in the arm-pits and groins;—so that the disease is characterized by buboes;<sup>b</sup> but the glands of the groins are more frequently affected than those of the arm-pits. Sometimes these glandular swellings, or buboes, come on at the first; and sometimes not till towards the end of the complaint. Besides them, however, there appear upon the surface vesicles of various sizes; the contents of which are frequently dark. There are, upon the surface, boils, carbuncles, and vesicles; and between them, and even where they do not exist, there are often vibices, petechiæ, and ecchymoses. These petechiæ, it is said, will sometimes rise into carbuncles;—where at first there was merely a little effusion or congestion of blood, there will sometimes, at last, be carbuncles. Occasionally, there is not sufficient power of the constitution,—not sufficient strength of inflammation, for carbuncles and buboes to arise. Just as in the case of the violent application of malaria, or the violent application of the poison of typhus-fever, and also as in cholera, persons will sometimes die immediately, without any reaction taking place.<sup>c</sup>

*Duration.*—The plague usually destroys life in from two to five days; but if a

<sup>a</sup> See Page 415.

<sup>b</sup> From *bubon*, the groin.

<sup>c</sup> Dr. Shapter ("Library of Medicine," Volume 1, Page 188) has described three varieties of plague:—1. *Simple* or *glandular* plague; which is rarely fatal in its termination, and but seldom characterized by any very urgent symptoms. 2. *Eruptive* plague; which is attended by a period of reaction, and occurs more frequently than either of the other varieties. 3. *Malignant* plague; in which the period of reaction is either entirely absent, or but very imperfectly developed; and death ensues with great rapidity.

person survive the fifth day, recovery is generally expected. Most people who are seized with this disease die; even though they enjoy every advantage of treatment and comfort. It is said that the disease may be had more than once.

*History.*—Some consider it a very ancient disease. The symptoms are mentioned by Hippocrates; and Dr. Bancroft contends that the disease is mentioned in the Bible; and that this was the affection under which the Philistines laboured, when they are said to have been smitten in the private parts, after taking away the ark. He says that the disease spread as they carried about the ark;—that it was a contagious disease; and the more they carried about the ark, the more the disease was communicated; till, at last, it spread from Ashdod to Ekron.<sup>a</sup> He considers that the Philistines probably received the disease from Egypt. Some consider that, as the Philistines were smitten “in the hinder parts,” they were afflicted with piles; but Dr. Bancroft contends that piles would not have killed them, in the way in which they perished.<sup>b</sup> However, I think there is this objection to Dr. Bancroft’s argument; that, in the book of Psalms, it is said, they were not only smitten “in the hinder parts,” but were put to a *perpetual* shame.”<sup>c</sup> This intimates that a chronic disease was left; but the plague would not have left a chronic disease of that description. It is stated that from fifty to seventy thousand persons were smitten by the disease. But whether Dr. Bancroft be right or wrong, the symptoms were distinctly mentioned by Hippocrates. It is a disease that almost always prevails in the Mediterranean, at Constantinople, at Venice, and all the various ports of that sea. It has likewise prevailed at Marseilles, Moscow, and London.

*It is Contagious, not Infectious.*—There can be no doubt whatever of its being a contagious disease; but it is rarely communicated without contact. It is, for the most part, believed to be a *contagious* diseases, in the strict sense of the word;—not *infectious*. One of the latest writers upon this subject (Mr. Madden, a surgeon) says, that if there be a deficiency of ventilation and cleanliness, so that the emanations from the patient are very much concentrated, it may be communicated by infection; but if there be any ventilation at all, then it can only be communicated by contact with the individual, or with something that he has touched. Some have denied, of course, that this disease is contagious; but there are proofs without end that it is. The case of Dr. Whyte, who inoculated himself and died, has been already quoted.<sup>d</sup> Dr. Duncan, in his “Medical Commentaries,” mentions similar instances.<sup>e</sup>

When the French army were in Egypt, about eighty medical officers died of it in one year. The next year, they employed Turkish barbers to dress the patients, and bleed them; and then only twelve medical officers died; but one half the bar-

<sup>a</sup> “They carried the ark of the God of Israel about. And it was so that, after they had carried it about, the hand of the Lord was against the city, with a very great destruction. And He smote the men of the city, both small and great; and they had emerods in their secret parts.”—(*First Book of Samuel*; Chapter 5; Verses 8 and 9.)

<sup>b</sup> “There was a deadly destruction throughout all the city. The hand of God was very heavy there.” (*First Book of Samuel*; Chapter 5; Verse 11.) The disease which proved *fatal*, however, would appear to have been something distinct from the emerods; for we are told, in the sixth verse, that “He destroyed them, and smote them with emerods;” and, in the twelfth, that “the men that died *not* were smitten with the emerods.”

<sup>c</sup> “He smote his enemies in the hinder part; he put them to a perpetual reproach.”—*Psalms* 78; Verse 66.

<sup>d</sup> See Page 304.

<sup>e</sup> Very different results have followed this operation. In some instances the symptoms of plague have appeared, while in others the only effect was slight local irritation;—as might be anticipated from inserting a poisonous fluid matter into the cellular membrane. But even had plague occurred in all these cases, no satisfactory conclusion could be deduced;—owing to the fact of their having been performed in situations where the disease was prevalent at the time. In order fairly to test the question, it would be necessary to institute a most unjustifiable series of experiments; namely, to inoculate with plague products persons living at a distance from the localities where this disease occurs, and who could have no communication (either direct or intermediate) with plague-cases, except through the matter with which the experiment is made.—“*Library of Medicine*,” Volume 1; Page 209.

bers died. It is said, that at Moscow, in 1771, all the assistant surgeons (amounting to fifteen) were seized with it, and of these three died; but the physicians, who did nothing but walk through the wards with a pen in their hands, generally escaped. The assistant-surgeons were here reduced to the same state as the barbers.

At Marseilles there had been no plague for fifty years, till 1720; when an infected vessel arrived. The disease, at that time, was distinctly traced to the arrival of an individual from an infected spot; and half the inhabitants died, in a short period after the arrival of the infected vessel. It is said that the plague had not been known at Moscow, for one hundred and fifty years, till they had war with the Turks; when two soldiers from an infected place arrived, and died; after which, eighty thousand perished from the disease in the city, and twenty thousand in the neighbouring villages. It is said, that the plague had not been known in Malta, for one hundred and thirty-seven years previously to 1813; and then the disease was brought from Alexandria.

Howard says that the plague of London, which occurred in 1665, was conveyed to a village in the Peak of Derbyshire, by means of some old clothes. He was so astonished at the absurdity of many medical men, in denying that it was contagious, that he writes as follows:—"Have not some of our professors sullied their names with the dangerous doctrine of the non-contagion of the plague? From no other cause than the error of the physicians, who constantly maintained that the disease then epidemic was not contagious, happened that terrible visitation which, in 1743, ravaged the city of Messina and its vicinity, with the loss of above forty-three thousand individuals, in the short space of three months." Most writers show, that persons who attended others labouring under the disease suffered; while those who ran away escaped it. The Turks are so satisfied of its being contagious, that when the disease prevails, they shut themselves up; and the Pacha holds communication with no person whatever. I think there can be no doubt of the plague being contagious,—in the strict sense of that word.\*

*Influence of Heat and Cold on its Progress.*—It is remarkable that great heat and great cold will stop the plague. It is a disease that will not bear great heat;—so that it has never been known to occur in tropical climates; and when the heat rises to a certain point, it stops. This takes place in Egypt about the twenty-fourth of June; and as that is the nativity of John the Baptist, he has the credit of putting a stop to the plague. The Catholics ascribe it all to him. From the intense heats, it is said never to appear in Upper Egypt; and it ceases altogether as the hot weather comes in. The winter also causes a cessation of it; and frequently renders exposure to a person labouring under it, perfectly harmless.

*Cause of its Cessation in London.*—From its being so contagious a disease, Dr. Wells considered that it was owing to quarantine laws, that we are not now troubled with this pestilence. He uses the following arguments:—1. Many persons ascribe our exemption from the disease to the fire of London; but the plague has not been known in London, since 1665; whereas the fire did not take place till 1666. The fire of London consumed only one-fifth of the town;—leaving untouched the Borough, Wapping, Whitechapel, Clerkenwell, St. Giles's, and the purlieus of Smithfield; which were among the dirtiest places. 2. Bristol has escaped for the same length of time as London, and yet there has been no fire in that city; and the improvements there began much later than in London. The Dutch are as cleanly as we are; and yet the plague continued there forty years longer than in England. 3. The town of Cracow is a very dirty place; and yet there has been no plague there for a century. 4. Ague alarmingly increased, and returned eleven years after the fire; and dysentery continued till the end of the

\* For very full details, and reasonings at great length on this subject, the reader is referred to the following work:—"Results of an Investigation respecting Epidemic and Pestilential Diseases; including Researches in the Levant concerning the Plague. By Charles Maclean, M. D.; Lecturer on the Diseases of Hot Climates to the Honourable East India Company." The second volume contains an account of the author's experience in a plague-hospital; where he himself took the disease, but recovered.

century, notwithstanding the improvements; and therefore he argues, *à fortiori*, that as the improvements could not prevent *dysentery*, they could not prevent the *plague*. 5. The plague is not known in India, China, and North America; where, in many places, they are filthy in the extreme. 6. The plague began first among the poor, who associated with the sailors of infected vessels. Dr. Wells contends that, from the time the quarantine laws were established, the plague has been unknown in England; and that, from the considerations I have now stated, the circumstance could not arise from the increased cleanliness, and general improvement of London; but from a strict adherence to quarantine laws.<sup>a</sup>

*Objections by the Non-Contagionists.*—[The objections made to these views, by those who maintain that the disease is solely caused by epidemic influences, are the following:—1. A miasm emanating directly from a plague-patient, or the transmission of the disease intermediately by fomites, are facts by no means conclusively proved; in truth, the whole statements in favour of contagion are imperfect and unsatisfactory. 2. Certain places, when the immediate neighbourhood was under the influence of plague, have not been kept healthy by means of quarantine regulations. It has often been shown, that in such situations some few cases have occurred, but that the disease has not spread; which immunity has been attributed to the ventilation and internal discipline rendering those within the cordon less susceptible of the epidemic influence. 3. Many of those in the most constant communication with the sick, do not take the disease; the attendants, who perform all the necessary offices, as well as the medical men, escape; and many who have advocated the doctrines of anti-contagion have ventured with impunity upon the more rash and hazardous experiments of tasting the secretions, wearing the clothes, and sleeping in the beds of those affected. Those engaged in burying the dead, are not more subject to plague than other persons; and even sexual intercourse has been known to take place, without communicating the disease. 4. The evidence of plague being communicated by inoculation, is any thing but satisfactory. It has already been remarked, that to make the experiment conclusive, the person to be inoculated with plague-matter should be living in some district far from the local or general influences of the disease. On the contrary, those cases previously referred to, where this method produced no results, go far to negative the communicability of the disease through the medium of pus, or other plague-products introduced into the system by inoculation. 5. The occurrence of sporadic cases is conclusive against the notion, that contagion is the sole origin of plague; and the existence of those cases, without spreading the disease, is a fact which militates greatly against its being contagious at all. It is evident that the occurrence of isolated cases in large cities, which is not unfrequent, is a fact totally irreconcilable with the doctrines of contagion, as sanctioned by its advocates. 6. When the disease becomes prevalent in a district, it is found to occur in situations and among individuals where there is the least possible communication with the infected; and it frequently breaks out in remote and separate parts of a town, without any traceable intercourse or communication. 7. In maritime towns, where it is said to have been imported, it frequently happens that those who are the first affected, live in parts which are distant from the shore, and therefore not in the nearest and most likely places to receive the infection. 8. It is found to arrive in many localities at the same time; and this applies both to the country and to towns. In the East, it is frequently observed to arise within a few days in places which are not only very distant, but in circumstances which prevented communication; and to occur, in like manner, simultaneously in different parts of the same town;

<sup>a</sup> We believe that, were they perfect and practically well carried out, which they certainly are not, they would yet be, comparatively speaking, useless. But they are, as now worked, not only useless, but most severe and vexatious incumbrances upon the liberty of the person; while the lazaretto—from the situations in which they are placed, from the nature of the buildings themselves, and from the ignorance of the medical men which are appointed to them—tend unnecessarily to harass and annoy the individuals condemned to confinement in them, as also to constitute them places where disease may be rather originated than prevented. “*Library of Medicine;*” Volume 1; Page 212.

—facts which evidently show a more diffused influence, than is probable on the supposition of human contagion. 9. Notwithstanding all the very curious and ingenious modes in which the propagation of plague has been said to have taken place, the possibility of which it requires a very large share of oriental credulity to believe, the disease is really very difficult to propagate by any means which as yet have been devised by man. Many instances of adventurous experiment, made without success, sufficiently prove this. 10. Numerous instances may be quoted, of large masses of persons moving from an infected district without carrying the disease with them. The contagionists state, that immense multitudes of hadjis, or pilgrims,—who go every year from Turkey to Arabia, through both Syria and Egypt,—are the instruments by which the plague is spread in the countries thus visited by them. So far, however, is this from being the case, that the marches of these people, in different years, take place at different seasons, while plague is a disease more especially of one season; and that, excepting when these marches of the Mussulmen coincide with the plague-season, their progress is not characterized by its occurrence; and, moreover, that many of the districts through which they pass, during their pilgrimage, are never known to suffer. In 1824, when the plague raged so fiercely in European Turkey, many thousand Turkish pilgrims passed through Alexandria, on their way to the Holy City; but in Alexandria there was only one case of plague; though no precautions were taken, and no quarantine regulations then existed to interrupt their progress. 11. Plague is a disease of endemic origin; and, therefore, all those cases which are said to have been caused by contagion, are really owing to endemic influences. 12. The spontaneous and sudden decline of plague at a particular season, disproves the operation of a contagious principle;—this being evidence, that plague is influenced by climatorial changes: a condition which the advocates of contagion do not suppose consonant with its laws. On the other hand, it proves plague to be owing to some endemic influence which has now ceased to exist. On this periodic cessation taking place, in the countries which are the most frequent seats of the disease, the inhabitants lose all dread; and from experience know, that without any evil consequences they may meet each other, visit the sick, and wear the clothes of those who have died. 13. Besides the above more general arguments against contagion, an inference to the same effect may be drawn from the fact, that before plague sets in, especially in such countries where it is of more rare occurrence, diseases of a putrid character and fatal tendency are prevalent; and that epizootic affections take place, and frequently cause great mortality among animals.\*]

*Period of Incubation.*—When the poison has been applied, the disease generally appears in from three to five days.

*Not communicated by the Dead.*—It is said that the disease is rarely caught from a dead body. When speaking of the innocuous agency of putrefied animal matter, I mentioned the statement of Howard;—that persons did not suffer from the stench of the putrefying dead bodies of those who had fallen victims to the plague.<sup>b</sup> I believe persons may touch the dead bodies, without fear of catching the disease; but touching their *clothes* is another thing. It is said by Dr. Bancroft, that all the Turks employed by the French to bury the dead escaped, with the exception of one individual. Howard says, that in Turkey people are not afraid to handle the dead bodies.

*Treatment.*—As to the treatment of the disease, I believe that one-half of those who have it perish; and therefore we must conclude that the treatment is not very successful. But we are told, that the treatment must be conducted on the same principles as in common fever. If there be a phlogistic diathesis, active bleeding, cold affusion, and calomel, are recommended; but, on the other hand, when there is debility, we must exhibit wine, quinine, ammonia, and (if Dr. Stevens be correct) the neutral salts, in great abundance. Of course those who follow one ex-

\* "Library of Medicine;" Volume 1; Pages 210 and 211.

<sup>b</sup> See Page 314.

clusive rule of practice, will kill a great many. Those who always bleed will destroy a great number; and those who always give brandy, will do the same. But Mr. Madden has compared the two modes of treatment. He says that, where bleeding has been had recourse to, the mortality has generally been very great; but where he gave strong brandy and water, and induced a copious perspiration, his success was very great. He also gave enemata of the same ingredients;—that is to say, hot brandy and water; he sponged the body with vinegar and water; soaked the head with vinegar; had hot poultices put on the buboes, till they gave pain; and cut into the carbuncles to arrest the mortification; and by this local and general treatment he was so far successful, as to save seventy-five patients out of a hundred. I should suppose that the period for a lowering plan, in this disease, is very short; and that stimulating treatment is preferable. The best antiphlogistic treatment would be, not to evacuate blood, but to apply cold water, and purge. From the accounts I have seen, I should think that active depletion would be very dangerous. The moment softness of the pulse is perceived, I should imagine that the treatment mentioned by Mr. Madden would be very proper.

*Nature of Plague.*—[The phenomena attending the development of plague during life, and the lesions observed after death, do not enable us satisfactorily to decide upon its proximate cause, or nature. Those writers who have entertained theories upon fevers generally, apply them most complacently to plague; and—without much effort, but with some little ambiguity,—reconcile all that takes place to their favourite views. We shall not, however, dwell upon the “considerable spasm and loss of tone in the extreme vessels” of Cullen; nor upon the “gastro-enteritis” of Broussais;—the frequent absence of which (even to the period of death) he explains, by saying it has not had time to develop itself; nor to the equally puerile views of another pathologist, who states plague to be an inflammation of the bronchial tubes; (comparatively speaking, a very rare seat of lesion in this disease;) nor upon several others which might be named; but shall content ourselves by giving a short abstract of the opinions entertained by Craigmiles and Bulard. The former of these writers applies the general view which he advocates; namely, that it is owing to derangement of the capillary system. In reference to the disease now under consideration, he says, that “the remote material agent which causes it, whatever that may be, acts upon the capillary vessels, immediately or secondarily through their contents, in every tissue and every organ of the human body. The result of which is, that the fluids are no longer freely transmitted through them;—so that there is produced a sudden and almost immediate retardation of the motion of the blood through the capillaries of the whole system.” He infers this to be the case from the four following circumstances:—“1. The arteries of the brain and the investments of the stomach, of the intestinal tube, and of the secreting glands, are distended with dark-coloured semi-fluid blood. 2. The vessels (of all the organs) are much loaded with dark-coloured fluid blood; which escapes immediately on the smallest incision. 3. In several of the organs—for instance, the brain, the lungs, the liver, the kidneys, and other solid organs, nay even in the muscles,—dark-coloured half-coagulated blood is found fixed in clusters of vessels;—so as to form dark or carbonaceous patches and masses. 4. Dark grumous blood is found, not only in the right chambers of the heart, but in the left auricle and ventricle; in which they are not usually found in ordinary death.” (“Practice of Physic.”)]

Bulard is not less ingenious. He states plague to be the contagious product of lymphatic absorption. This view is grounded upon the statement, that the only symptom which has been remarked as alone and distinct from any other at the commencement of the disease, is pain in the lymphatic glands. This is at first but a slight throbbing, becoming more violent and continued, and ultimately succeeded by swelling and buboes. This change in the lymphatic glands is the only lesion which is to be found totally isolated from all others, and it is consequent upon changes in the lymph; and therefore each, during the local affection, is to be considered only as consecutive to this disorder in the lymphatic system; in which

consists the simple original affection,—the essence of the disease, and without which no general disturbance could have occurred. This view Bulard supports, on the grounds that the whole system of lymphatic vessels, whether going from or to the gland, is not diseased, but only the glands themselves; therefore he argues that, as the glands are always diseased and the vessels never, it is evident that the malady is not conveyed by continuity of tissue, but that the diseased principle is introduced into the lymphatic circulation; and therefore the alteration of the lymph is cause and reason sufficient for the phenomena of diseased absorption, the pathological effects of which are displayed on the glands. The disease, therefore, arises from a change in the lymph. This constitutes the primary affection; the secondary effect of which is, that as this degeneration in the lymphatic fluids becomes more or less advanced, the blood itself becomes decomposed by the morbid lymph entering into its composition by the venous circulation. It thus loses its normal qualities, and then causes a general disturbance,—a deep disorganization in all its functions; in short, all the derangements of a true poisoning. From this moment it loses its physiological character, and assumes one entirely peculiar to itself: and hence are to be explained the lesions met with throughout the system—the livid colour of the stomach, the swollen state of its mucous membrane, the softened state of the spleen, gorged as it is with black grumous blood, the enlarged and softened condition of the heart, &c.; in fact, every lesion which has been mentioned. Hecker, in his account of “the black death,” reverses the theory of Bulard;—stating that the blood is first attacked through the atmospheric poison acting on the organs of respiration; and that the inflammation in the lymphatic glands and other organs, is only consequent upon the change thus effected in the vital fluid.<sup>a</sup>]

## SECTION XI.—MALIGNANT PUSTULE.

The two inflammatory and pustular diseases of which I have next to speak, are both derived from brutes. The first is what is called by some writers “the malignant pustule;” by the French it is called “pustule maligne;” and I rather think it is this disease (though I am not certain) that is called by the Germans “milz-brand.” In this affection there is produced a carbuncle, very similar to the carbuncle of plague. I do not imagine that the disease is by any means well understood; but its existence is an undoubted fact.

*Causes.*—When animals have died of a particular disease, in which there are pustules tending to gangrene, it has occasionally happened, that the individuals who have skinned them have had carbuncular pustules (of a dark colour) take place on the surface, and have perished from them. It is said occasionally to have arisen from persons having merely touched the blood of an animal, which was killed while labouring under this disease. Indeed, one instance is recorded of a butcher being seized with a gangrenous inflammation in the face, and speedily dying, after having put between his lips a knife, with which he had killed a bullock labouring under this disease. Some suppose that disease of this description (a carbuncle tending to gangrene, and bearing a resemblance to the carbuncle of plague) is never produced but by the contact of the blood, or the secretions, or the body of a brute which has died of this disease; or of something which the body has touched; but Rayer, who gives an account of this disease, considers that, now and then, it occurs simultaneously and sporadically. However, I should hardly think him correct. It is possible that the person may have touched something, which had been in contact with the animal previously to its having its skin taken off. The animal may have been sent to market, and contact is possible (just like the infection of scarlet-fever and small-pox) without our being able to trace it.

*History.*—It has been described by Morand (a French surgeon) in the history

<sup>a</sup> “Library of Medicine;” Volume I; Pages 207 and 208.

of the French Royal Academy, for 1766. He there gives cases of butchers and others, who have been affected with gangrenous erysipelas, and carbuncles. He thinks it can arise, even without an abrasion of the surface, if the blood of the animal be applied. Enaux and Chaussier described the "pustule maligne," in their work on the Treatment of Bites, published in 1755;—that subject being followed by a short account of malignant pustules. Two instances are mentioned in Hufeland's Journal, for 1822, of diseases of this description, which proved fatal to two men. They had been wetted, in the performance of venesection, with the blood of a cow labouring under the disease. In each case, the chief inflammation found after death was peritoneal; and also they had buboes. The pustules, or carbuncles, of this disease, have generally been observed among veterinary surgeons, shepherds, tanners, blacksmiths, butchers, and labourers;—in fact, among all those persons who were most likely to come in contact with brutes labouring under the affection. It is said usually to display itself on those parts of the body which are uncovered; such as the face, neck, hands, shoulders, or arms;—all those parts being uncovered, in many descriptions of work.

*Contagious, not Infectious.*—I never saw an instance of this disease. I believe that, in general, it is not *infectious*; but merely *contagious*. There is an account of many people being seized with a disease in 1818, at Ostiano, in Italy. Thirty-five persons visited an ill-ventilated stable, which contained three cows and ten horses; one of which had laboured under an offensive discharge from the nostrils for twelve months. Eleven of them were seized with the disease; and all but one died. Violent pyrexia, pains, spasms, boils, and at last a large carbuncle, characterized the first stage; gangrenous vesicles, and a typhoid fever, were the chief features of the second. Whether this was the same disease I do not know; but if so, it would appear that where there is a want of ventilation, and many animals are crowded together, it may be infectious.

*Treatment.*—It is at present rather an object of curiosity than of practice; for I believe that no treatment does good. Some persons, however, recommend the application of the cautery to the carbuncles, as soon as they appear. It is supposed, by Rayer, to bear a very great resemblance to the plague in human beings; but it is very likely, notwithstanding, to be a different disease.

## SECTION XII.—EQUINIA.

*Diseases of Brutes communicable to Man.*—That the diseases of man are communicable to brutes, is a well established fact. The measles (according to good authority) have been imparted to sheep; and, in like manner, have trichoma and plague been each communicated to brutes. On the other hand, several diseases may be communicated from brutes to men;—as the cow-pox by vaccination, the mange from dogs,<sup>a</sup> and hydrophobia;—the probability being that, in each case, the disease may be given back from man to brutes. The cow-pox certainly may;<sup>b</sup> and Magendie has himself reproduced hydrophobia in a dog, by inoculation from the froth of a rabid man. To these instances may now be added "glanders;"—a disease well known from its destructive ravages among horses, but which has only recently been observed to occur in the human subject.

*History.*—The fact of its occurrence in man was first established, or (at least) rendered highly probable, in this country, by Mr. Coleman; and by three cases which came under the notice of Mr. Travers, and were reported in his work on "Constitutional Irritation,"<sup>c</sup> as being very like cases of glanders; but were described by him (as if glanders in man were not possible) as instances of a diseased state of the constitution. Mr. Coleman had taken some of the glanderous matter from one of these cases, and inoculated an ass with it. Glanders and farcy were the result,

<sup>a</sup> In which case the disease in man assumes the appearance of itch.

<sup>b</sup> See Page 440.

<sup>c</sup> See Page 350.

and death ensued in twelve days. Further proof, moreover, was obtained; yet the facts were alluded to at the time by Mr. Travers as a matter for wonder, that disease could be communicated from man to a brute, and yet the disease in the brute not be the same as that which existed in the man.

*Case 1.*—Of the possibility of this disease occurring in the human subject I was perfectly ignorant, when a young man was admitted into St. Thomas's Hospital, under the care of Dr. Roots, on the nineteenth of March, 1829.

The upper half of the face—including the eyelids and nose, with a portion of the cheek on each side (especially on the right)—was greatly tumefied;—so that the eyes were closed. The eyelids and swollen portions of the cheeks, were red and hot, dry and shining; but the nose was dark-coloured; and its right half black, cold, and senseless. From around the gangrened portion of the nose, and some other points, a little pus was oozing, as well as a thin dark-coloured fluid; and *from the nostrils a thick discharge (of a deep yellow colour, here and there a little bloody) was taking place.* It was very copious from the right nostril. Several hard phlyzacious pustules existed on and immediately around the nose,—still principally on the right side; and in various parts of the trunk and extremities. Tumefactions were observed in both fore-arms, and on the back of the right hand. Some of these were hard; others softening into suppuration. The temperature was high; the pulse 136, and sharp; the tongue white, and rather dry. The respiratory murmur was indistinct at the lower part of the chest, and the respiration quick and difficult. The gums were slightly turgid. It was stated that, twelve days previously, he had been attacked by pain in the right hypochondrium, extending up the chest, attended by dyspnoea, and rigors; that he took ten grains of *Pilulæ Hydrargyri*; and the next day felt quite well. The pain and dyspnoea, however, returned on the day following; but subsided at the end of the week; under the use of leeches and purgatives. On the Sunday, five days before his admission, a pimple was said to have appeared on the right side of his nose. While this increased and suppurated, the surrounding parts swelled and grew red; and the state of things became such as I have already described.

Fourteen ounces of blood were taken from the arm, and became both buffed and cupped. Some of the tumefactions were cut into, and large quantities of pus discharged. Lint soaked in a solution of the chloride of soda, and covered with a poultice of stale beer-grounds, was applied over the nose, and was renewed every hour; and a common poultice was applied to the abscesses which had been opened. An ounce of castor-oil was given; and the diet restricted to slops, milk, and arrow-root.

Late in the evening, two greenish and very offensive stools were passed involuntarily; and a little delirium was observed. Tumefactions had begun upon both legs, one upon the left hand, and one upon the right elbow. The next morning, more tumefactions were seen upon the extremities. They were red,—as all the others had been; but the latter had now acquired a purple tint; and the wounds looked dark. The forehead was swollen and red; and more pustules had formed upon the face. There was constant agitation, frequent delirium, and profuse diarrhœa; and there had been no sleep. *Mistura Cretæ* was ordered; sixteen leeches were applied to the temples; and strong beef-tea was added to the diet. In the evening, the diarrhœa was checked; but the upper lip had grown very dark. Sordes encrusted the teeth; the surface, still hot, was covered by a profuse sweat; and many new, hard pustules, were seen upon the trunk and extremities. The pulse had become soft, and was small and rapid. Twenty-five minims of *Tinctura Opii* were given in the first dose of the *Mistura Cretæ*; and one grain of the *Quinæ Disulphas* every four hours was prescribed. The *Oleum Terebinthinæ* was substituted for the solution of the chloride of soda.

He was calm after taking the opium; but, about four o'clock in the morning, was observed to breathe with more difficulty, to be unable to swallow, and to be constantly delirious. From that time he sunk gradually; and expired at six.

I was not present at the inspection; but understood that there were proofs of a

violent pleuro-peripneumonia in the lower part of the right side; and that two ounces of healthy pus were found between the adherent lung and diaphragm. A dark red patch existed in the stomach, and several at irregular distances throughout the intestines. The mucous membrane of the stomach was very lacerable at that spot. The other viscera, and all the contents of the head, as well as the veins of the extremities, were reported healthy; but the mucous membrane of the nostrils was not examined. The abscess which had been opened in the back of the right hand, communicated with the joint of the metacarpal bone of the middle finger; but those on the arm did not communicate with the elbow.

The appearances suggested to me the idea that some deleterious matter had been introduced into the system. I inquired if he had probably been in the way of catching such a complaint, if he knew of any one similarly affected, and if he had taken any other food than was good and habitual to him, or was used by the rest of the family. But all these questions were answered in the negative; and therefore, when asked by the pupils my opinion, I declared myself perfectly at a loss.

*Case 2.*—On the following June, I found a young man lying in one of my beds, in precisely the same state. The nose and surrounding parts were exceedingly swollen; so that the left eye was closed completely, and the right nearly. The tumefied parts were hot, and of a bright red, with the exception of an inch of the left half of the nose; which was of a mulberry-colour;—precisely the same state of things, that occurred in the other young man.<sup>a</sup> A profusion of deep-yellow tenacious mucus, with a few streaks of blood, exuded from each nostril; but particularly from the left. Several hard phlyzacious pustules existed on the nose and adjacent parts; as well as on the arms, thighs, and legs; and each was surrounded, in the latter situation, by a blush of red. A patch of the same colour was observed on the left elbow. His pulse did not justify bleeding; it was rather an undulation than a pulsation. I ordered him beef-tea, wine, and sulphate of quinia; but he was dead in a few hours.<sup>b</sup>

As in the former case,<sup>a</sup> the father was present at the inspection; and he would not allow the head to be examined, or any incisions that would disfigure to be made. Many parts of the lungs were gorged with blood and frothy fluid, and the corresponding bronchial branches were very dark; numerous papillæ, with pointed black summits, were seen at the end of the ilium; and clusters of minute grayish black points throughout the small intestines, and most abundantly at the commencement of the duodenum. The walls of the left ventricle of the heart were very thick. Nothing, however, was detected, either peculiar or important, or calculated to throw the faintest light upon the disease;—a disease which to me (I confess) was truly awful;—from its suddenness, rapidity, gangrenous source, and seemingly uncontrollable power.

While I was standing at the bed-side, considering in silence the case before me, its identity in nature with that which I had seen in March,<sup>a</sup> appeared certain; and the disease appeared, as certainly, to be a specific eruptive fever. I therefore stated to the pupils, that while at the occurrence of the former case,<sup>a</sup> I had only the idea of some deleterious agent (without being able to imagine of what kind), I now felt satisfied that this agent in the two cases was a morbid poison;—a poison furnished by a living system under the same disease. I put the same questions to this patient and his friends, as in the former instance;<sup>a</sup> and received the same negative answers.

The morbid poison could not have been generated in the system of the patients themselves: because their clean appearance, and the good circumstances and respectability of the friends with whom they lived, were such as to preclude the generation of any morbid poison. Although acting but seldom upon human beings in this country, still its residence among us was certain, if it really existed; for

<sup>a</sup> See Case 1, Page 457.

<sup>b</sup> A drawing was made of each patient; that of Dr. Roots's was executed by Mr. Solly; and the other (which contains two representations,—the one *before*, and the other *after* death) by Mr. Alcock.

neither of the patients had been near persons from abroad. Yet no other person in the vicinity of either patient, or anywhere that either had been, was known to have had such a disease. The morbid poison, and its residence among us (of which I entertained no doubt), together with the circumstance of its rarely affecting human beings, now seemed fully explained by the supposition, that the disease was one common to some of our brutes; and the profuse discharge from the nostrils, and the tumours and tubercular pustules on the surface, agreed with the supposition that this disease was the glanders.

*Case 3.*—Soon after this, a “Fatal Case of Acute Glanders in the Human Subject” was reported, in the “London Medical Gazette,”<sup>a</sup> by Mr. Brown,—a surgeon in the second regiment of dragoons; which, on examination, I found to agree precisely with the cases above described. The man was seized, on the night of the sixteenth of April, with rigors, headache, and slight irritability of the stomach;—all the symptoms which usher in an eruptive fever. However, he had great pains and stiffness of all the large joints; and these increased to an alarming degree. The left shoulder was rather swollen, though not inflamed; but the tumefaction became considerable, and of a livid hue. Similar swellings, but smaller, took place on the arms, legs, thighs, and sacrum;—exactly as in these cases in the hospital. The tumours were insensible and hard; but, in the cases in the hospital, the tumours were soft. They were of a chocolate-colour; but acquired a deep vermilion hue, and soon became of a dark brown. One appeared upon the left temple; and the eye-lids became tumefied. *The right nostril was gummed up with an inspissated discharge.* The posterior fauces were much inflamed, and nearly of a purple hue. Several watery pustules (which I have termed “phlyzacious”)<sup>b</sup> rose above the skin, in various situations around each of the tumefactions. On examination after death, a cluster of tubercles was found in the cellular membrane exterior to the pericranium<sup>b</sup> of the left superciliary ridge, and in the right frontal sinus;—exactly resembling (according to Mr. Brown) those observed in the frontal and other sinuses of the horse, after acute glanders. On dividing the various livid tumours down to the bone, the muscles appeared perfectly decomposed, and of a dark livid colour; and under each was a cluster of gray circular tubercles. The existence of these tubercles is so common in the glanders of horses, that one French writer takes this for a tubercular disease; and it is described under that name in a French Veterinary Dictionary. The army-surgeon adds:—“It appeared that the patient had had, for some time, the sole charge of a glandered horse, which had been destroyed on the very evening of his attack; and that he had skinned him; and exerted himself a good deal, in cutting up and burying the carcase. But these circumstances did not at first create the least suspicion: and his complaint was considered a very severe case of acute rheumatism; and was treated as such.”

*Case 4.*—About a fortnight or a month afterwards, a general practitioner at Clapham, to whom I mentioned these cases, told me of a case which he thought was of the same description. A young man (a pupil of the Veterinary College, and the son of a veterinary surgeon at Clapham) had been seized with a very severe acute affection of the knee-joint (apparently rheumatic;) and with severe pains;—just like the other cases. He proposed that I should see the patient; but the father put it off till the next day, and in the interim the son died. Before death there was a copious sero-mucous discharge, occasionally a little bloody, from the eyes and nose; the Schneiderian membrane was excessively red and nearly excoriated; and the eyes were closed. A pretty abundant eruption, very similar to small-pox, but larger and hard, appeared in different parts; but particularly the neck. There was scarcely any sleep; but occasionally delirium, and at length convulsions: and the patient died. Unhealthy pus was found in the absorbents of the arm; and the bursa of the knee contained a large quantity of pus, with flakes of

<sup>a</sup> Volume 4; Page 134. (No. 83; July 4, 1829.)

<sup>b</sup> From *περι*, about; and *κρανιον*, the cranium.

coagulable lymph. He appeared to have had under his care, at Clapham, a horse affected with "farcy-glanders."<sup>a</sup> The ring-finger of the right hand, and the absorbents and axillary glands, became all at once inflamed and painful; but whether after any wound or abrasion, could not be satisfactorily ascertained. The finger suppurated and was opened; and, a few days afterwards, he was seized with headache and pains in his limbs; which pains were considered rheumatic. There were afterwards pimples on the face; and a profuse discharge from the Schneiderian membrane.

*Communicated to Man by Brutes.*—The perfect correspondence in the symptoms and progress of those cases that had fallen under my observation, with those of Mr. Brown's case,<sup>b</sup> convinced me that an active investigation would trace the origin to horses, from which they had received the contagion. I had a great deal of trouble in endeavouring to ascertain this fact, and indeed I could not prove it at last; but I found that these men (although in an occupation that one would suppose would never lead them near horses,) had actually been in the neighbourhood of glandered horses. Further than that I could not ascertain; but it is a very singular circumstance, that this was satisfactorily proved. I found, with respect to my own patient, that he was a whitesmith, at Lambeth. I went there, and inquired whether he had had any thing to do with horses; taking it for granted, that, as a smith, he had. They told me that he had never been near horses;—that he was a *white-smith*. However, I went to the workshop, and found it situated in a mews. I then asked if there had been a glandered horse in the mews; to which the father replied—"No;" but one of the men immediately said—"Why, don't you recollect there was a glandered horse in the stable, for six weeks, just next the corner where Tom used to work?" He then showed me that the boards which separated the stable from the whitesmith's shop were so defective, that the discharge from the animal's nostrils had come through; and occasioned so great a stench, that the young man frequently said he should not be able to work, unless the horse were taken away. I learned, that when this horse was being led to the knacker's, about a month before the commencement of this disease, it fell down exhausted at the door of the forge; and that he went and patted it about the head as it lay; and took hold of the head while the rest endeavoured to make the animal rise. I also found that he had a number of pimples on his face, which were raw; and his father said he recollected that his son had got a habit of wiping his nose with the back of his hand. So far I went; and, though this is not proof, yet these are singular facts.

With respect to the man that came first to St. Thomas's,<sup>c</sup> he was a tailor; and, tailors not being famous for horsemanship, I almost despaired of being able to trace any connection between him and a horse. But at last I found, that the next-door neighbour of the man to whom this lad was apprenticed, had kept a worn-out pony in a filthy wretched shed, opposite the two houses. I ascertained that the animal had glanders, and was afterwards killed on this account; that this youth was in the habit of harnessing it, and getting into a little cart which it dragged, to have a ride. Nothing is more likely, than that he had brought some of the matter from this horse in contact with him.

An examination of the history and progress of these, and other cases which had occurred in Germany,<sup>d</sup> led me to conclude that the cases in question were those of true glanders, and that man is susceptible of its contagion, on coming in contact with animals labouring under it. My reasons for this opinion are the following:—  
1. There is a perfect similarity and uniformity of the symptoms and course of all the acute cases of the affection; and they are quite distinct from those of any other disease. There is a perfect correspondence between the post-mortem appearances in cases that have been properly examined, and those that present themselves in the horse. 3. Each of these persons had been in communication with a glandered

<sup>a</sup> See Page 461.

<sup>b</sup> See Page 459.

<sup>c</sup> See Page 457.

<sup>d</sup> See Rust's "Magazin für die Gesammte Heilkunde;" Volumes 11 and 17.

horse; though the occupations of some of them had rendered this extremely improbable. 4. Glanders were produced in asses, by inoculation with matter taken from some of these cases.

*a. Appearance and Varieties in the lower Animals.*

*Varieties.*—Although it would be foreign to the character of this work to enter into a minute description of glanders as it occurs in the lower animals, still, as the disease may (and, as we have seen, does occasionally) occur in man, some notice of it is rendered necessary. Glanders may appear in two forms;—first, as ulceration of the nostrils; and, secondly, as tumours arising in various parts of the body, combined with corded or elevated lines in the neighbourhood of the tumours, formed of what are thought to be the absorbents. When the disease is limited to the former symptom, it is called “glanders;” when to the latter, “farcy.” The two, however, are the same disease, though distinct in name; and, from “glanders,” the affection will at length become “farcy.”<sup>a</sup>

*Acute Glanders in the Horse.*—The pituitary<sup>b</sup> membrane is very red, and very much inflamed; and presents little erosions, which take place rapidly, and become chancres (if we must, in compliance with custom, so call them); with edges thicker and more exuberant than those of the milder form of the disease. Sometimes the lips and the end of the nose swell; and afterwards the ulcerations commit more extensive ravages, and give rise to a discharge of a purulent appearance, and occasionally of a disagreeable smell. A fetid, purple, and perhaps bloody sanies, is mixed with it from time to time (at least in some instances); and, at length, the nasal membrane looks gangrenous. The discharge continues, and becomes more abundant; even blood issues from the nose. The sublingual glands, which are much swollen in all the forms of the disease, are more painful than in the mild acute glanders. The conjunctiva and nasal eyelid (“membrana nictitans”) are at first inflamed, and injected with blood; and afterwards acquire a violet hue. The eyelids swell, and the eyes discharge. The local phlegmasia soon extends to the surrounding parts; respiration becomes laborious; the superficial vessels are successively congested; and the animal dies, in spite of all we can do;—frequently in a few days, at other times after a longer or shorter interval. If the disease is protracted, the symptoms occasionally, though rarely, relax; and the inflammation declines. The animal then appears partially to regain its powers, and may be to a certain degree useful; but the state of the pituitary membrane, and of the *auge*, and the permanence and character of the nasal discharge, show that the acute stage has degenerated into the chronic. It is in this form, especially, that attacks of glanders may be considered epizootic. That violently acute glanders is always speedily fatal, and never becomes chronic, is disproved by the following fact:—In a stable of eighteen horses and three asses, all of which were affected, ten died within the first days of the attack; four, after the violence of the disease had abated, remained stationary for two months, and then were cut off by a return of the inflammatory symptoms;—a relapse into the acute stage. The seven which survived presented all the symptoms of chronic glanders, and worked in the country nearly a year, when it was thought proper to kill them.<sup>c</sup>

*Chronic Glanders in the Horse.*—The symptoms of chronic glanders in the

<sup>a</sup> Mr. Vines (in his work on glanders) says, that when the skin only is affected,—as with buds, ulcers, or œdematous swellings,—the symptoms are called “farcy;” but when the mucous membrane of the nostrils and lungs partakes of the disease, and becomes ulcerated,—with a discharge of unhealthy matter from the nostrils, and swelling and induration of the submaxillary lymphatic glands,—it then takes the name of “glanders;” but without any real difference being necessary in their treatment, although one set of symptoms may exist independently of the other.

<sup>b</sup> From “pituita,” *phlegm*.

<sup>c</sup> Dictionnaire de Médecine et de Chirurgie Vétérinaires.” Article, “La Morve;” Pages 458 and 459. (Third Edition.)

horse, are thus detailed by Mr. Blaine:<sup>a</sup>—"An increased and diseased secretion from the membranes of one or both nostrils, continually flows in small or large quantities. This discharge is seldom at first perfectly purulent; but is more glairy, thick, and not unlike the white of egg, and it sometimes continues thus for a long time; at others, it soon becomes purulent; but even then there is always a degree of visciduity and gluiness in it, that sticks the nostrils together (as it were) from its tenacity; differing from other pus, and which very circumstance strongly characterizes the complaint. The general colour of the Schneiderian membrane becomes changed, first to a violet colour, and afterwards to a leaden hue. As ulceration takes place, the discharge becomes bloody, and sometimes sanious and offensive;—which is always the case where the bones prove diseased. From an absorption of the morbid matter from the nose, by the lymphatics of the part, the lymphatic maxillary glands under the jaws (through which these vessels pass) become swollen and tender; and, as one side of the head only is sometimes affected with the glandered running, in such case one lymphatic gland only is tumefied; and, of course, the one of the affected side."—"The disease sometimes remains long without producing ulceration; at other times, on the contrary, an ulcerating process quickly appears. The ulcers have a very peculiar character. They are not unlike the venereal chancre; but usually commence by small limpid bladders; which soon ulcerate into a sore of a particular kind; and where there are several of them, they are always placed high in the course of the lymphatics."—"As the disease advances, much of the Schneiderian membrane becomes ulcerated; till, at length, the bones prove carious. At an uncertain period of the disease, the lungs become affected; when hectic symptoms soon follow, with tubercles which ulcerate; frequent vomiceæ also form and burst; there then appear cough, emaciation, and weakness in the loins; the hair feels dry, and falls off on being handled; the matter from the nose increases in quantity, becomes sanious, fetid, or bloody; and is coughed up by the mouth also; and, in this state, the animal dies."

*Farcy in the Horse.*—[The farcy generally appears in the form of small tumours (called by farriers "buds"), or small ulcers, about the legs; sometimes on the lips, face, neck, or other parts of the body. These tumours are, in some cases, so small, so few in number, and create so little inconvenience to the animal, that for a time they escape observation; at other times they are larger, more numerous, painful to the touch, and spread more rapidly; and, in these instances, a general swelling of the limb often takes place, particularly when the hind legs are attacked; and some degree of lameness ensues. The tumours (or "buds") are at first hard; but soon become soft, and burst;—degenerating into foul ulcers, of a peculiar appearance. The edges of the skin surrounding the ulcer, terminate abruptly; and the surface of the sore has a pale glossy appearance. The lines of communication between the "buds" or ulcers, are generally very observable; particularly when they occur on the inside of the limbs, where the superficial veins are large;—as in the thigh. They consist of what the farriers call "corded veins;" but, in reality, are inflamed and enlarged lymphatic or absorbent vessels."<sup>b</sup>]

#### *b. Appearance and Varieties in Man.*

*Varieties.*—I propose to call this disease "equinia" when it appears in the human subject,—as indicating its communication from the horse; for the same reason that "cow-pock" has been called "vaccinia." It may occur as true glanders, characterized *primarily* by ulceration of the nostrils; in which case I would call it "equinia catarrhalis;" or as farcy characterized by tumours in various parts,—*"equinia apostematosa."* Equinia may be either acute or chronic; but it has been observed more frequently, I believe, in the chronic form. The three cases, re-

<sup>a</sup> In his "Outlines of Veterinary Art."

<sup>b</sup> "A Treatise on Veterinary Medicine. By James White." Pages 7 and 8.

ported by Mr. Travers,<sup>a</sup> are examples of chronic equinia; though not reported as such by him. The other cases which I have detailed,<sup>b</sup> may be considered as instances of acute farcy and glanders.

*Symptoms of Equinia Catarrhalis.*—[The disease ordinarily presents the following phenomena in its progress, when it occurs in the acute form. Articular or muscular pains, in some cases simulating rheumatism, followed by subcutaneous, circumscribed, painful swellings (the probable result of angeo-leucitis); which either undergo superficial mortification, or are converted into abscesses, containing either laudable or sanious pus;—a yellowish, viscous, nasal discharge, of limited quantity; issuing, in the great majority of cases, from *both* nares; and first observed from the fourth to the sixteenth day; accompanied, in some instances, by a similar excretion from the mouth or eyelids;—occasional tumefaction of the nose and adjoining parts followed by gangrene in one-eighth of the cases;—in very rare examples, swelling of the submaxillary lymphatic glands, or depositions of pus therein; and, pretty frequently, inflammation of the throat and tonsils;—a peculiar pustular eruption, differing from all varieties hitherto observed; namely, gangrenous bullæ, appearing (towards the twelfth day of infection) on the face, arms, thighs, and anterior surface of the trunk; and sometimes preceded or accompanied by profuse fetid sweats; a rapid and full pulse at the outset; subsequently weak, depressible, and sometimes intermittent; and, as death approaches, extremely small and frequent;—diarrhœa, with watery stools, of a cadaverous smell, and occasionally containing dark coloured blood;—dental sordes;—dry, brown tongue;—tympa-nitic abdomen, with hardly any abdominal tenderness;—thirst, in a few cases;—difficult deglutition;—occasional vomiting, especially towards the close;—no *typhoid maculæ* on the surface;—violent cerebral symptoms, terminating in delirium, coma, and death.<sup>c</sup>]

M. Rayer distinguishes three varieties of the acute form of this affection;—the pustular, the gangrenous, and the pustulo-gangrenous.—“In some cases, the most striking phenomena consist of a pustular cutaneous eruption, a thick and glutinous nasal discharge, and a typhoid aspect. In others, the symptoms of nasal lesion are obscure; while the external characteristics (the pustular eruption and gangrenous affection of the skin) predominate. Again: pains in the limbs, purulent deposition in various parts of the body, and inflammation of the lymphatic vessels and glands, form, in the outset, the most striking features of another set of cases, still more strictly analogous in character to the acute farcy-glanders of the horse. Lastly: there are others more violent and promptly fatal; in which all these morbid changes and symptoms appear rapidly and at once, a few days after vague initiatory phenomena.”<sup>d</sup>

*Symptoms of Chronic Equinia Catarrhalis.*—The following case of chronic glanders, will best illustrate the symptoms in this form of the affection:—Thomas Gue, aged 50, was admitted on the thirtieth of April, 1835, under my care. He had been a sailor during the greater part of his life; but has lately followed the occupation of a groom. About two months since, his master having a glandered horse, he administered medicine to the animal, and washed his mouth; he also cleaned the nose with a sponge and warm water. He does not recollect that any portion of his hands were abraded of cuticle; but he had an open sore on his lips;—the consequence of a blow from a hammer. The horse occasionally sneezed in his face, which he wiped with the same cloth that he had used for the horse’s mouth and face. About three weeks prior to admission, he was seized with the following symptoms:—a dull aching pain across the brows and in the eye-balls; his nose felt stuffed; and there was a considerable discharge of thick, yellow, offensive pus from one of the nostrils; no ulcers were discernible on the pituitary membrane; but, from the patient’s statement, they probably existed in the more remote

<sup>a</sup> See Page 156.

<sup>b</sup> See Pages 457 to 460.

<sup>c</sup> Analysis of “Rayer on Glanders and Farcy in Man,” in the “British and Foreign Medical Review,” for July, 1838. (Volume 6; Page 118.)

<sup>d</sup> Rayer on Glanders and Farcy in Man; Page 642.

parts of the nose. The throat, on pressure, was rather painful, and the lymphatic glands were enlarged. He had also cough, and expectorated matter of a similar character to that discharged from the nose. His health had not been disturbed until about two days previously to admission; when he lost his appetite, and was seized with a pain in the epigastric region. This man recovered under the use of kreosote as an injection. "At a later period, sometimes after several months, tumours begin to appear in different parts; and their evolution is accompanied by rigors, nausea, delirium, general febrile disturbances, and frequent slimy evacuations. From this state the patient seldom recovers, but in general sinks gradually."<sup>a</sup>

*Chronic Equinia Apostematosa.*—[In this form of the disease, the nasal membrane at first remains sound; and small tumours gradually appear about the face, trunk, and limbs. These break;—producing an unhealthy discharge; and are attended or followed by purulent collections in the joints, or various parts of the body. The disease may terminate fatally in this manner; but the nasal affection often comes on at a later period.<sup>a</sup>]

*Causes.*—Among the various diseases of the lower animals to which man is susceptible, equinia is the most readily communicable of them all. According to the testimony of the best veterinarians, it is contagious (in the restricted sense), not infectious;<sup>b</sup> it is therefore only communicated by contact with the diseased secretion from the mucous membrane of the nostrils in glandered horses, or the pus produced in tumours on other parts. To render its contagion effective, abrasion of the surface is necessary; as it is believed, by most veterinary surgeons, that glandorous matter never excites the disease in the horse, even if applied to the pituitary membrane, while the surface is entire.<sup>c</sup>

*Period of Incubation.*—[There occurs in this, as in other contagious diseases, a variable though limited period of incubation. Thus, after the inoculation of glandorous matter, a period of from two to eight days, or more, elapses before the occurrence of any notable symptoms. At the end of this time, the evidences of local irritation appear at the injured part; its extension follows;—as is proved by the condition of the neighbouring lymphatic glands and vessels, and by general febrile phenomena. In some instances these local symptoms were slight, and easily relieved; the patients even appeared on the brink of recovery, when the essential and specific symptoms of glanders supervened. When the disease is contracted by *infection*, the invasion is marked by fever; attended by gastric symptoms, diarrhœa, or pains of the limbs.<sup>d</sup>]

*Duration.*—[The duration of acute and chronic equinia, is very various. In the former, death may occur in a few days; but, in the greater number, life has been prolonged beyond the twelfth day, and in some cases to the thirtieth. The chronic variety may last a month only; a few tumours and pustules slowly form, and disappear under curative measures; sometimes ten months have elapsed before the fatal termination occurred.<sup>e</sup>]

*Treatment.*—All attempts to cure the acute form of this disease have hitherto

<sup>a</sup> "Library of Medicine;" Volume 1; Page 406.

<sup>b</sup> See Page 300.

<sup>c</sup> The opinion here expressed by Dr. Elliotson, is no longer general. Dr. Eck, of Berlin, in a recent and valuable paper, thus expresses himself:—"Though the glandorous nasal discharge is recognised as the chief vehicle of infection, and (on this account) the use of harness, mangers, drinking-vessels, &c., which have been in contact with glandered horses, and are liable to be brought in contact with the pituitary membrane of sound animals, is especially to be feared; yet it can hardly be doubted, that the contagion may exist in the other excretions; nay, that occasionally, as in damp stalls, infection may take place without any observable contact;—probably through the medium of respired air." ("British and Foreign Medical Review;" Volume 6; Page 116.) This opinion is also adopted by Rayer; who has divided his collection of cases into those,—"where no local results of inoculation are observed; the first symptoms being those of a general infection of the system;" and those,—"where the earliest phenomena are angeioleucitis, local phlebitis, or diffuse cellular inflammation in some region of the body, usually the arm; while the lesions and symptoms of *glanders* do not appear until subsequently." (Rayer on Glanders; Page 643.)

<sup>d</sup> Analysis of Rayer, on Glanders; in the "British and Foreign Medical Review;" Volume 6; Page 117. (No. 11; July, 1838.)

<sup>e</sup> "Library of Medicine;" Volume 1; Page 406.

failed. Rayer is decidedly hostile to bleeding, either topically or generally;—as tending to accelerate prostration, stupor, and local gangrene. On the other hand, bark and other tonic antiseptics have proved equally fruitless. Rayer recommends the immediate excision of the swollen glands, in the early stages of the disease; and if the local inflammation following this operation, or resulting from the inoculation alone, were intense, “debridement” and mercurial frictions might (he presumes) be employed with advantage. He also recommends the employment of repeated purgings, and the exhibition of large doses of acetate of ammonia;—a favourite remedy with veterinary surgeons. As to topical treatment, he advises the free incision, and subsequent cauterization of the pustules and abscesses; while the patient’s strength is supported by tonic drinks, and generous wine diluted with gaseous water. Solutions of the chlorides,—used as gargles, taken internally, or injected into the nostrils,—have been recommended;—on account of their powerful antiseptic properties. Turpentine—either in the form of warm embrocations applied externally, or administered internally in small and frequently repeated doses—has also been recommended.<sup>a</sup> The patient’s excessive thirst should be assuaged by the use of soda-water, or slightly acidulous drinks.

In two cases of chronic glanders which have come under my notice, the employment of kreosote has been attended with complete success. In one case, that of Thomas Gue already mentioned,<sup>b</sup> the injection of a solution (consisting of one minim of kreosote to an ounce of water) into the nostrils, effected a cure in about three weeks. In the other case, this man’s master, I administered it internally, in addition to the injection, with the like result. From one to three minims may be administered daily.

A few words as to the sanatory applications of the facts which are now so prominently before us. The subject is one of the highest public importance; and demands the serious consideration of those on whom the care of the public health devolves. The facts peremptorily behave all persons who have any thing to do with glandered horses, instantly to destroy them; and in all cases to do so, unless a cure be discovered for the disease, or some new mode of treatment be proposed. I am told by Mr. Yonatt and other veterinary gentlemen, that at least forty-nine out of every fifty glandered horses ultimately perish of the disease. Then why suffer animals so frightfully dangerous, to linger out the remainder of an existence which they pass so wretchedly, and run the chance of giving the disease to other animals and to men? With such evidence before us, every glandered horse in the kingdom ought to be killed forthwith;—unless it is thought fit to institute some new investigation into the treatment of the disease. Nothing can be more wrong than to keep glandered horses alive for the little work which may, in spite of the debilitating effects of the disease, be forced from them. Let their owners but reflect for a moment on the multiplied opportunities which occur for contagion between these animals; the innumerable occasions for smearing, with a poisonous matter, the various parts of the stable; the risk of depositing it on the grass when turned out; and, above all, of giving it to man; who must assuredly perish by it in the most dreadful manner;—for no remedy is known for it. The effect is awful to me beyond any thing that I ever witnessed in disease. Here we may have young men in all but perfect health one week,—after acute suffering, offensive discharges, and sores and putrefaction, corpses the next. I thought when I had seen the fatal cholera, that I had witnessed the acme of sudden suffering and death; but the man who is glandered presents a scene quite as heart-rending to our view, as the cholera-patient.

<sup>a</sup> Dr. Peddock, in a letter to Dr. Elliotson, published in the “Lancet” for February 19, 1831, (No. 390; 1830-1, Volume 1, Page 639,) has related a case of glanders in the horse, which was successfully treated with oil of turpentine. The analogy between oil of turpentine and kreosote, in many respects, explains this success.

<sup>b</sup> See Page 463.

## CHAPTER VI.

## PURPURA.

I SHALL now describe an affection, which consists in extreme *congestion* of the skin, without any *inflammation*; and is characterized by the presence of petechiæ, vibices, and ecchymoses on the skin; which occur throughout the body, on the conjunctiva, and even within the mouth, and in the interior of the body;—so that the blood will actually be poured forth on the various viscera. This disease is called at present, in this country, “*purpura*.”<sup>a</sup> It was formerly called “*petechiæ sine febre*,” or “*hæmorrhagia petechialis*.” Rayer has, very properly, separated it from inflammatory diseases; and has placed it in the order “*congestia*.”

*Pathology*.—It is a very singular disease, and sometimes occurs in the most opposite circumstances;—occasionally with great debility, weakness of pulse, and exhaustion; sometimes with the most inflammatory state of the system.<sup>b</sup> Although the *skin* is not actually in a state of inflammation, yet the *system* is in an inflammatory condition; as is proved by the buffy and cupped state of the blood.

*Analogous to Scurvy*.—It bears a great affinity to scurvy, and some fancy it is the same disease; but I cannot subscribe to that opinion.<sup>c</sup> It is a disease that frequently happens without any constitutional affection. I have seen persons going about with it, and yet quite well in other respects; and in other cases, persons have died *with* it. There is no affection of the limbs, and no sponginess of the gums, as in scurvy. The disease, too, has often arisen without any evident cause; whereas scurvy (I believe) never takes place, except from a deficiency of proper food.

*Symptoms and Varieties*.—If the disease occur merely on the surface of the body, forming patches, it is called “*purpura simplex*.” But frequently there is extensive bleeding from the mucous surfaces of the mouth, stomach, and intestines. I once had a patient, who died from bleeding within the head (“*apoplexy*”); and a clot of blood, which had oozed from the vessels of the pia mater, was found under the arachnoid membrane. Sometimes the spots are large; and sometimes there is ecchymosis. There is no inflammation or tenderness of the particular parts. It appears to be a mere congestion of blood. In severe cases, the patient is pale; he looks as if he were in a state of anæmia; and I dare say the blood is deficient in quantity. On the other hand, I have seen children with many hundreds of these spots upon them; and yet running about perfectly well. Sometimes there would appear to be a little inflammation connected with this congestion; attended with great tingling, and even little wheals; and then it is called “*purpura urticans*.” Frequently there is such tenderness of the vessels in old people, that if they rest upon their arm, or knock their hand against a door,—so as to produce the slightest bruise,—ecchymosis will take place; and that has been called “*purpura senilis*,” although, indeed, it is not this disease at all. It conveys the idea that it is the same disease; but it is merely such a tenderness of the vessels, that the slightest contusion produces ecchymosis. Persons may have the disease for many years, at the latter part of their life; and yet be perfectly well. We are often consulted by patients on this occurrence; and it is right to know that it is *ecchymosis*, and should not be called “*purpura*.” It is merely a bruise; and may be produced on old persons with the greatest facility.

*Causes*.—Petechiæ may take place in many circumstances;—frequently in typhus-fever; frequently in small-pox, between the pustules; and sometimes in scarlet-fever. It is very common to meet with them in dropsy, where there is great

<sup>a</sup> From πορφύρα, a shell of a purple colour.

<sup>b</sup> See Page 364.

See Page 233.

debility; they very often occur where there is extreme dyspnœa; and sometimes in phthisis, where there is extreme difficulty of breathing. But there may be such debility of the vessels, that they allow the blood to ooze forth. Or there may be an impediment to the return of the blood; and the blood may be *forced out*. Frequently, however, no reason can be assigned for the disease. The person may be living as usual; when, all at once, the disease makes its appearance.

*Treatment.*—I do not think there is, at present, any satisfactory or universal mode of treatment; but we must treat it according to the particular circumstances in each case. In mild cases, moderate bleeding, or mere purging, answers very well; and I think I have satisfied myself that purging with *colchicum*, answers better than other things. I have made observations upon this medicine, in other cases. I have purged with colchicum, and with other things; and the difference has been very greatly in favour of colchicum. I am sure we shall get rid of this disease sooner, by purging with colchicum, than by any other means. Where there is strength of pulse, it is necessary to bleed, and bleed freely. I have seen patients lose two or three pints of blood, in a few days, with great relief; and they have got well. A great number of cases are of this inflammatory nature; but by no means all.

Others are of a different description; and wine, bark, and good nourishment, must be given. I recollect a case (which occurred in a child) where there was merely moderate debility; and the child was out every day. The disease was not intense, but these petechiæ existed; and under good nourishment and tonics the patient got well. But in extreme cases, it is necessary to do more than this. It is necessary to give wine and opium; and to treat the patient as we should if he were sinking under typhus-fever, or confluent small-pox with typhoid symptoms.

*Turpentine.*—Where there is hæmorrhage, I have no doubt it would be best treated by oil of turpentine. As the latter restrains hæmorrhage from the alimentary canal, better than any other medicine, I have no doubt it would restrain it under this peculiar affection. One of the most severe, and most successfully treated cases that I ever saw, was at St. Thomas's Hospital, under the care of Dr. Roots. There were petechiæ, vibices, and ecchymoses, in every part of the body; together with great congestion of the liver;—so that the right hypochondrium was distended. Blood was also poured forth from different cavities. The patient was bled, and took oil of turpentine; and he got well rapidly. Every one who saw him, must have supposed that he was near death. I was much disappointed in a case of my own, which I treated in the same way. Apoplectic symptoms came on; and, on opening the patient, a clot of blood was found on the brain.

---

## CHAPTER VII.

### DISCOLORATIONS OF THE SKIN.

BEFORE proceeding to those affections which are of a structural nature, I may perhaps make a few remarks on those diseases which consist in a discoloration of the skin. Some of these are really not affections of the skin itself. For instance: in jaundice the skin is yellow; in chlorosis the skin is exceedingly pale; and likewise in anæmia. On other occasions, however, the skin is itself discolored; and among these affections are mentioned “sun-spots;” and that blackness or blueness of the surface, which is induced by the continued exhibition of nitrate of silver.

*Lentigo.*—[“Lentigo,”<sup>a</sup> or “freckle,” is the name given to the multifarious small, rounded, brownish-yellow or fawn-coloured stains that appear upon the face,

\* From “lens, lentis,” a *lentil*;—from its resemblance to lentil-seeds.

bosom, hands, and neck;—more especially in individuals of fair complexion and delicate skin. Sometimes these spots cover the whole surface of the body. They are generally most abundant in childhood and youth; and are much less seen in dark complexions, in manhood, and in old age. They are evidently induced by exposure to light and heat; although they do not seem to result from the direct action of the sun's rays. The parts upon which they appear, never evince the slightest symptom of derangement. The best mode of preventing their appearing or increasing,—which they generally do in spring,—is to avoid carefully a too vivid glare of light, and to protect the skin by some slight covering. They require no treatment.

*Ephelis*.—"Ephelis"<sup>a</sup> is characterized by one or several irregular-shaped broad patches, of a light or dark yellowish-brown; occurring most frequently on the front of the neck, chest, abdomen, groins, and inner part of the thighs; generally accompanied with itching, and sometimes with slight desquamation of cuticle.

The patches of ephelis generally appear slowly; and remain several weeks, or even months. They often occur in individuals enjoying the most perfect health, but sometimes appear to depend on a particular state of the system;—such as that which occurs on the approach of the menstrual period, and during pregnancy. Violent excess may sometimes occasion their appearance; but they have often a connection with disease of the digestive organs. They occasionally occur upon the face of pregnant women;—covering it with a kind of mask.

The patches of ephelis, at first small, increase slowly; and attain a size varying from that of a sixpence, or less, to that of the palm of the hand. These patches, being separated by intervals of healthy integuments, give the skin a very peculiar appearance. But at a later period they coalesce, and cover extensive continuous surfaces with a single coloured patch; in the breadth of which, here and there, some spots of healthy skin are seen; and at first sight appear like so many morbid stains. These patches are usually attended with itching; which is increased by exposure to heat, by slight moral impressions, by indulgence in spirituous liquors, and by scratching. Sometimes, though rarely, slight cuticular desquamation takes place.

The two latter symptoms distinguish the patches of ephelis from "pityriasis versicolor;"<sup>b</sup> in which there is no pruritus, and much desquamation. The red copper-colour of syphilitic blotches, will always prevent their being mistaken for ephelis; and if, in some rare cases, the yellowish cast of a patch of *nævi* should cause any doubt, the duration of the latter, and the knowledge of its being congenital, will soon clear up the mystery.

*Treatment*.—The patches of ephelis readily disappear on the use of the sulphurous water-bath, with or without the internal use of the same remedy. The waters must first be taken mixed with two-thirds of barley-water or milk; and their quantity increased by degrees. When the itching is very troublesome, a lotion containing one ounce of sulphuret of potash dissolved in two pounds of water, may be frequently applied. Gentle aperients may, at the same time, be administered; and all stimuli should be strictly forbidden.

*Nævi*.—Under the common title of "*nævi*," two very different forms of congenital affection of the skin are included. The one—termed also "*spili*,"<sup>c</sup> "*nævi pigmentares*,"<sup>d</sup> or "*mole*,"—is met on all parts of the body, is of various sizes, and cannot be considered as a disease of the skin. The other—"nævi vasculares" ("*mother mark*")—is owing to an original morbid condition of the vascular system of the part affected. Of these, some are quite superficial, often met with on the face, and are of the colour of claret or port-wine. They remain indolent; and appear to be formed by a simple dilatation of the arterial and venous vessels, distributed to the part of the skin affected. Others are somewhat elevated, and of the same deep-red colour; these are of a far more dangerous nature, and are formed of

<sup>a</sup> From *επι*; and *ήλιος*, the sun

<sup>b</sup> See Page 403.

<sup>c</sup> From *σπίλος*, a spot.

<sup>d</sup> From "*vasculum*," the diminutive of "*vas*," a vessel.

<sup>e</sup> From "*pingo*," to paint.

erectile vascular tissue. Their size is very various: sometimes a small speck not bigger than a pin's head, and of a bright-red colour, rapidly acquires such dimensions as to render it necessary to have recourse to a surgical operation. The treatment of the vascular erectile tumours is, indeed, altogether surgical.

*Vitiligo*.—"Vitiligo"<sup>a</sup> is a partial colourless state of the skin, either congenital or accidental, occurring in irregular white patches of various extent. It occurs frequently among negroes, and occasionally among whites. The "*vitiligo hydropicorum, gravidorumque*"<sup>b</sup>—a name given by Frank to the small white lines which are seen upon the abdomen of females after delivery, or those which succeed to ascites—does not really consist of patches of vitiligo; but of small lacerations of the corpus mucosum, induced by the distension of the parts. The patches of vitiligo are white; and when they occur on parts naturally covered with hair, the latter is also white. It is not uncommon to observe vitiligo upon the scrotum.<sup>c</sup> In aged persons, these patches acquire sometimes considerable extent: they never cause pain, heat, or itching; and require no treatment.<sup>d</sup>

## CHAPTER VIII.

### ORGANIC DISEASES OF THE SKIN.

THE organic affections of the skin are, for the most part, of a tubercular nature. The most important of these are lupus ("noli me tangere"), cancer,<sup>e</sup> elephantiasis, and ichthyosis.

#### SECTION I.—LUPUS.

Lupus<sup>f</sup> is a disease more frequently treated by the surgeon, than by the physician; and is an affection that is particularly seen upon the face, around the nose, and upon the upper lip.

*Characters*.—Lupus is characterized by tubercles which are rather oval, and frequently flat; and of a brownish-red or livid colour. They increase and terminate in ulceration; and an ichorous discharge is then poured out, and concretes into crusts. It appears on the nose and cheeks, and sometimes upon the ears and chin; but it is calculated that, eight times out of ten, it attacks the nose. The parts around become harder and harder; suppuration goes on to ulceration; till, at last, a great degree of destruction is produced. It is exceedingly intractable.

*Varieties*.—One variety occurs in scrofulous children; and frequently gives way, sometimes to one application, and sometimes to another;—occasionally, perhaps, spontaneously. But there is another description, which produces deep ulceration and extreme pain; and frequently appears to be somewhat allied to cancer. This is called "*noli me tangere*;" from its generally becoming worse, if interfered with by medical men.
